mechanical heterogeneity of acutely injured lungs by the suppression of air-liquid interfaces and the reopening of collapsed or liquid-filled areas. Partial liquid ventilation (PLV)[123] with perfluorocarbons has thus been tested as an alternative to conventional gas ventilation for the treatment of acute respiratory failure. In experimental models of acute lung injury, PLV was shown not only to improve gas exchanges and lung mechanics dose-dependently[124] but also to decrease histologic lung lesions.[125] However, when both large perfluorocarbon and tidal volumes were used, PLV led to a high incidence of barotrauma.[126] The mechanical properties of rat lungs flooded with saline in order to reduce the aerated volume were studied after injurious mechanical ventilation with and without intratracheal perfluorocarbon instillation. The instillation of a low dose (3.3 ml/kg) of perfluorocarbon in these flooded lungs not only improved lung mechanics but also decreased permeability alterations.[26] The effect of perfluorocarbon dosing was further tested in rats ventilated with high tidal volumes having previously healthy[127] or preinjured[128] lungs: Lower doses (10 mL/kg) of perfluorocarbon were protective, whereas larger doses (13 and 16 mL/kg) aggravated lung edema. A clinical trial comparing conventional ventilation to PLV with low (10 mL/kg) and high (20 mL/kg) doses of perfluorocarbon yielded consistent results. Indeed, both PLV groups exhibited not only higher plateau pressures and poorer oxygenation than the conventional ventilation group but also fewer ventilator-free days and a trend toward greater mortality, as well as a higher incidence of pneumothoraces (17% versus 6%, $p < 0.05$).[129] The failure of PLV when large perfluorocarbon volumes are used, and thus high plateau pressures generated, highlights the clinical relevance of VILI.

Conclusion and Clinical Applications

The experimental concept of VILI is undeniably relevant to clinical practice.[93] High-volume injury contributes to the mortality of patients with ARDS and may be reduced by decreasing V_T and plateau pressure. On the other hand, the concept of low lung volume injury that should benefit from high levels of PEEP has not received the same convincing clinical confirmation, given the negative survival data from three randomized controlled trials comparing two levels of PEEP,[2,38,39] but still, current guidelines, which mainly rely on a meta-analysis of these three trials,[130] recommend using high PEEP levels for the most severe ARDS patients.[131] Thus the ideal ventilatory strategy has yet to be determined. For the time being and until further evidence is obtained, one may put forward the following conclusions:

- Tidal volume reduction should likely apply to all mechanically ventilated patients, and a 6-mL/kg V_T with a plateau pressure <28 cm H_2O is typically used because of the lack of readily available tools that allow for measuring the aerated lung volume at bedside, thus limiting the possibility to titrate individually an ideal V_T. In the meantime, the analysis of the respiratory mechanics can provide meaningful tools, which can indicate that the ventilation strategy is likely to be safe.[103,106]
- Superprotective ventilation strategies relying on techniques such as extracorporeal CO_2 removal or extracorporeal membrane oxygenation (ECMO), rendering it possible to drastically reduce the V_T applied (ie, in the range of 3 and 6 mL/kg), have yet to be assessed by well-designed clinical trials.

- Prone position applied early to patients having an ARDS with a PaO_2/FiO_2 ratio <150 mm Hg may improve patient survival.
- Although use of PEEP remains the cornerstone of management of hypoxemia during ARDS, use of high levels of PEEP should likely be restricted to patients with the most severe forms of ARDS.
- Ventilatory management of ARDS is not yet deeply supported by evidence, but basic physiologic principles remain helpful to clinicians.[62,99,132,133]

CHAPTER 53

Asthma

Steven L. Shein, Richard H. Speicher, Howard Eigen, Alexandre T. Rotta

PEARLS

- Patients with severe acute asthma exacerbations should be promptly and aggressively managed in the emergency department with inhaled β-agonist agents, inhaled ipratropium bromide, oxygen, and a systemic corticosteroid. Patients who fail to improve or who further deteriorate should be admitted to the intensive care unit for escalation of therapy and a higher level of monitoring.
- Standard treatments include administration of intravenous fluids, oxygen, β-agonist agents by intermittent or continuous nebulization, ipratropium bromide, parenteral corticosteroids, and intravenous infusion of a β_2-agonist agent. Other therapies available in the intensive care unit include intravenous infusions of magnesium sulfate and methylxanthine agents, and breathing helium-oxygen mixtures.
- Failure to respond to treatment can lead to further deterioration and the development of respiratory failure, necessitating noninvasive ventilatory support or even intubation and mechanical ventilation. When needed, ventilation should be initiated with a strategy that avoids dynamic hyperinflation. Select patients may benefit from inhalational anesthetic agents for bronchodilatation, bronchoscopy to relieve airway obstruction or atelectasis resulting from mucous plugging, or extracorporeal life support.
- Aggressive medical treatment and a mechanical ventilation strategy that minimizes dynamic hyperinflation result in low morbidity and near-zero mortality rates in patients with critical or near-fatal asthma.

Asthma is a highly prevalent chronic disease that affects both children and adults. It is the most common medical emergency in the pediatric population. Despite adequate treatment and access to medical care, patients with asthma are at risk for episodic acute respiratory deterioration, commonly known as reactive airway disease exacerbations or asthma attacks. These episodes vary greatly in severity, ranging from those that are easily managed in the outpatient setting by increasing corticosteroid and bronchodilator therapy to severe episodes with intense airway obstruction that rapidly evolve to respiratory failure.

Several terms are used to denote severe asthma attacks, including *status*

asthmaticus, acute severe asthma, critical asthma, and *near-fatal asthma*. Definitions vary among sources, and many consider *status asthmaticus* to be an outdated term.[1-5] For this text, *acute severe asthma* is defined as an asthma attack unresponsive to repeated doses of beta-agonists and requiring hospital admission,[1] *critical asthma* is defined as acute severe asthma necessitating ICU admission,[6,7] and *near-fatal asthma* is defined as critical asthma that requires endotracheal intubation and mechanical ventilation.[7]

Epidemiology and Risk Factors

Asthma is the most common chronic illness in childhood, affecting 9.5% of all children in the United States.[8] Overall global prevalence is approximately 11% to 13% and varies widely, from approximately 5% in some Asian and Eastern Europe countries to nearly 25% in parts of Central America, South America, Oceania, and the United Kingdom.[9] Asthma is a common reason for hospitalization, with approximately 150,000 pediatric asthma admissions occurring in the United States annually.[10] It is also a common comorbidity among children hospitalized for other reasons, present in 21.8% of all-cause pediatric hospitalizations.[11] In some countries, including the United States, asthma hospitalizations are becoming less frequent, but admissions are increasing in other developed countries.[10,12,13] Even in areas where the incidence of acute severe asthma is decreasing, admissions to the pediatric intensive care unit (PICU) are increasing. In New Jersey, the incidence of critical asthma increased from 0.09 to 0.31 per 1000 children between 1992 and 2006, and 35% of acute severe asthma admissions received ICU care during the most recent epoch.[14] In Ohio, ICU utilization averages approximately 25% among six children's hospitals, with greater than 40% of hospitalized children receiving ICU care at some centers.[15] Rates of positive pressure ventilation for asthma have increased in the United States and Spain.[10,12] Among critical asthma patients in the United States, 5% to 12% are treated with invasive mechanical ventilation, and 3% to 5% are treated with noninvasive ventilation.[14,16,17] Intubation prior to PICU admission is common and associated with shorter duration of mechanical ventilation.[16] Despite this increase in critical care utilization, mortality rates from acute severe asthma (<0.1%), critical asthma (~0.3%), and near-fatal asthma (~4%) are quite low. Many of the deaths from asthma occur in patients who suffered prehospital cardiac arrest.[7,12,14,16]

Risk factors for severe asthma exacerbations are of particular importance to the practicing intensivist (Box 53.1). Critical asthma is disproportionately more common in boys, Hispanic children, and African-American children.[16] Risk factors for near-fatal asthma include African-American race, older age, concurrent pneumonia, and the presence of comorbid conditions.[7,10,14]

Box 53.1

Risk Factors for Near-Fatal Asthma

Medical Factors

Previous asthma attack with the following:

- Admission to intensive care unit

- Respiratory failure and mechanical ventilation
- Seizures or syncope
- Pa_{CO_2} >45 torr
- High consumption (>2 canisters per month) of β-agonist metered-dose inhalers
- Underuse of corticosteroid therapy

Psychosocial Factors

- Denial of or failure to perceive severity of illness
- Associated depression or other psychiatric disorder
- Noncompliance
- Dysfunctional family unit
- Inner-city residents

Ethnic Factors

- Nonwhite children (black, Hispanic, other)

The majority of patients with asthma who progress to near-fatal asthma or cardiac arrest do so prior to arrival at the emergency department or during the first stages of therapy.[7,18] Therefore early identification and close monitoring of patients at high risk for near-fatal asthma could be advantageous. High-risk patients often have a history of ICU admissions,[19] mechanical ventilation,[4,19] seizures or syncope during an attack,[20] Pa_{CO_2} greater than 45 torr,[4,19] attacks precipitated by food,[19] or a history of rapidly progressive and sudden respiratory deterioration.[5] High-risk patients are likely to use more than two canisters of β-agonist metered-dose inhalers per month[21] and often are poorly compliant or are receiving insufficient steroid therapy.[22,23] Denial and failure to perceive the severity of an attack are factors frequently associated with near-fatal asthma.[24,25] Although unquestionably some patients at risk for near-fatal asthma simply ignore early warning signs and do not seek medical attention, a subgroup of patients actually lacks normal perception of disease severity. Some patients with near-fatal asthma exhibit reduced chemosensitivity to hypoxia and blunted perception of dyspnea.[26] Other patients have a decreased perceptual sensitivity of inspiratory muscle loads and display abnormal respiratory-related evoked potentials.[27]

Although many of these high-risk factors are commonly present in patients with near-fatal asthma, they fail to identify a significant number of cases. In one case series, 33% of patients who died of asthma were judged to have a history of trivial or

mild asthma, whereas 32% had never been admitted to the hospital with an asthma exacerbation.[5] The Collaborative Pediatric Critical Care Research Network (CPCCRN) reported that 13% of 260 children with near-fatal asthma had no prior history of asthma and that only 37% of known asthmatics had required hospitalization in the 12 months preceding the episode of near-fatal asthma.[7] Some of these patients may in fact have what likely represents a distinct clinical entity known as sudden asphyxial asthma, a condition marked by acute onset of severe airway obstruction and hypoxia that rapidly leads to cardiorespiratory arrest in patients known to have only mild asthma or no asthma history at all.[28,29]

Pathophysiology

Asthma is primarily an inflammatory disease and, as such, it is marked by highly complex interactions among inflammatory cells, mediators, and the airway epithelium[30] (Fig. 53.1). Functionally, asthma is characterized by variable airflow obstruction and airway hyperresponsiveness associated with airway inflammation. Though various inflammatory phenotypes cause clinical asthma, asthmatic patients commonly have airway inflammation dominated by eosinophils, T_H2 cytokines, and IgE.[31] Pathologically, it is marked by mast cell degranulation, accumulation of eosinophils and CD4 lymphocytes, hypersecretion of mucus, thickening of the subepithelial collagen layer, and smooth muscle hypertrophy and hyperplasia.[32]

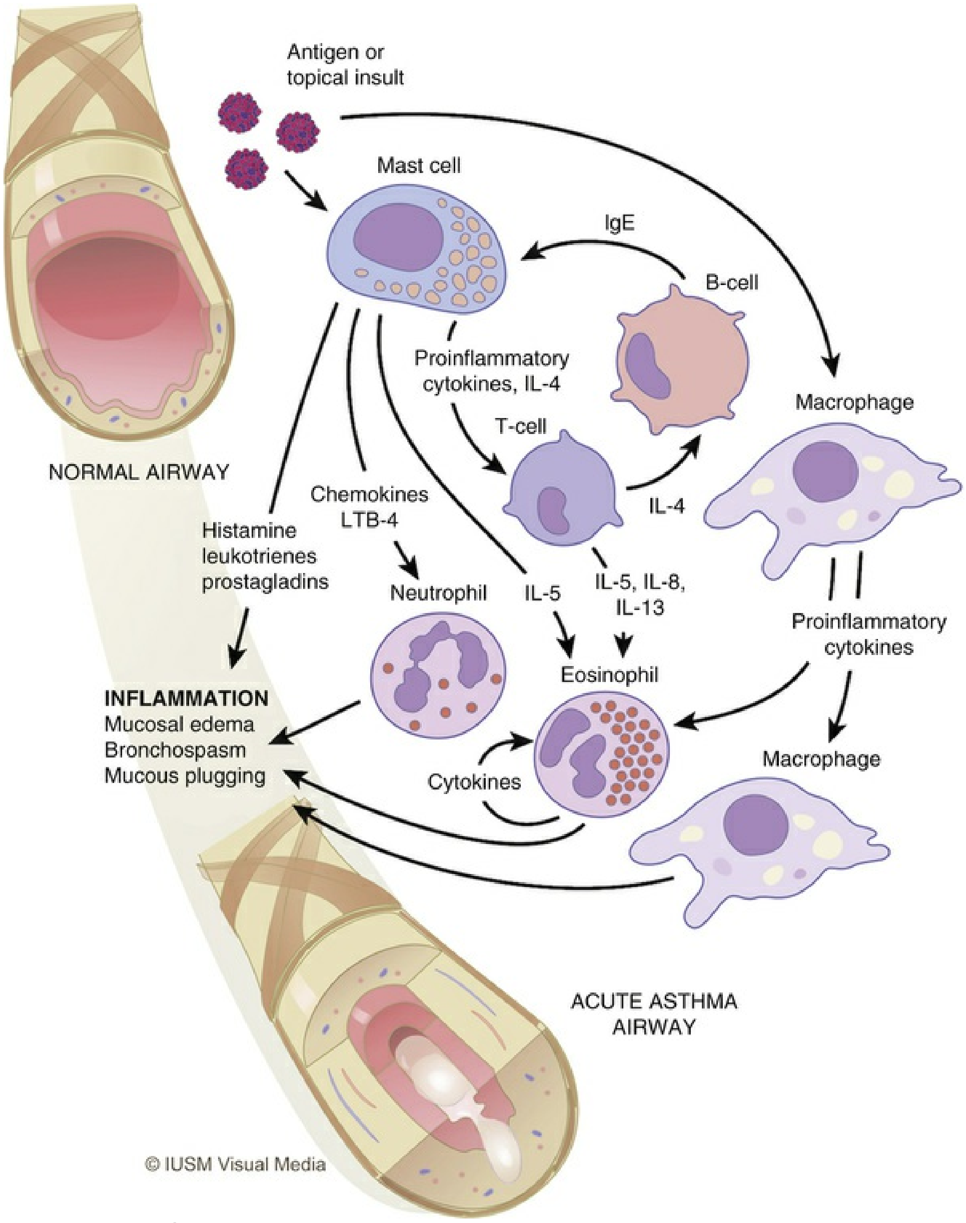

FIG. 53.1 Cellular and humoral mediators that lead to mucosal edema, bronchospasm, and mucous plugging in patients with acute asthma. *IL*, interleukin; *LTB-4*, leukotriene B-4.

Mast cells, eosinophils, neutrophils, macrophages, and T lymphocytes are central to the derangements that occur during an acute attack (see Fig. 53.1). The usual cascade begins with the activation and degranulation of mast cells in response to allergens or topical insults. Mast cells release mediators including histamine, prostaglandins, and leukotrienes that cause acute bronchoconstriction. Additionally, the mast cells promote activation of T lymphocytes via allergen presentation. The inflammatory process is then amplified by T-lymphocyte release of cytokines and chemokines, predominantly T_H2 cytokines, such as interleukin (IL)-4, IL-5, IL-8, and IL-13.[33] The presence of these T_H2 cytokines leads to further augmentation of the inflammatory process through excessive production of immunoglobulin E (IgE) by B cells, stimulation of airway epithelial cells, and eosinophil chemotaxis. IgE stimulates mast cells to release leukotrienes, whereas interleukins (particularly IL-5)

promote maturation and migration of activated eosinophils into the airway.[34] This highly inflammatory state results in stimulation of airway epithelial cells and continued augmentation of the inflammatory process by further release of leukotrienes, prostaglandins, nitric oxide, adhesion molecules, and platelet-activating factor. This process results in overproduction of mucus and in epithelial cell destruction, leading to airway plugging and denuding of the airway surface. Disruption of the epithelial surface exposes nerve endings, resulting in hyperirritable airways[35] that become more susceptible to spasm and obstruction when challenged by subsequent exposures to allergens and irritants.[36] Airway irritants that trigger acute asthma include cigarette smoke and inhaled particulates,[37] respiratory tract viruses,[38] psychologic stress,[39] and cold air.[40] The mucus secreted in the airways of asthmatics contains large amounts of cellular debris and is thicker than in normal persons.[42] Mucus hypersecretion may be a principal cause of respiratory failure in persons with severe asthma and has been underappreciated as a factor in respiratory failure.[41-43]

Inflammation-mediated airway edema, mucus hypersecretion, airway plugging, and bronchospasm lead to the severe airway obstruction seen in patients with severe asthma exacerbations. The resulting obstruction and increased airway resistance create an impediment for inspiratory and expiratory gas flow, which leads to deranged pulmonary mechanics and increased lung volumes.[41]

Airway plugging can result in ventilation/perfusion mismatching and an increased oxygen requirement. Hypoxemia is nearly universal in patients with a severe asthma attack, but generally it is easily corrected with supplemental oxygen[44] and is only weakly correlated with pulmonary function abnormalities.[45] More frequently, heterogeneous airway plugging and obstruction lead to regional alveolar hyperinflation associated with reduced perfusion, resulting in a significantly increased pulmonary dead space. Most patients with acute asthma exhibit an increased respiratory rate in attempt to achieve a higher minute volume and compensate for the ventilation abnormality. In asthmatics with acute exacerbations, airway obstruction results in significant prolongation of the expiratory time. The subsequent breath is initiated before the last one has emptied leading to dynamic hyperinflation. The small airways collapse and close at a higher than normal lung volume contributing further to dynamic hyperinflation and air trapping. At higher lung volume there is a higher alveolar driving pressure to empty the lung, which should serve as an adaptive mechanism. However, the net result in acute asthma is high-energy use. Expiration becomes active with the use of the abdominal muscles. At high lung volumes the lung is less compliant and the inspiratory accessory muscles are engaged to help move an adequate tidal volume[46,47] (Fig. 53.2).

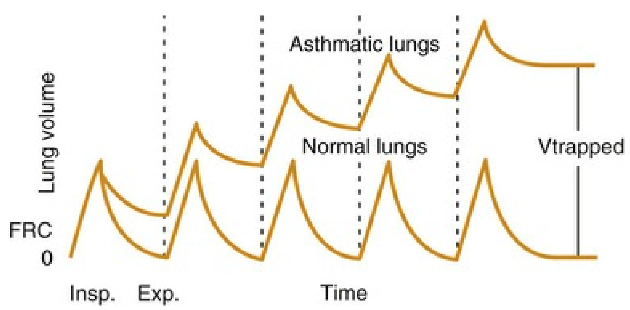

FIG. 53.2 Mechanics of dynamic pulmonary hyperinflation in the setting of severe airflow obstruction. The next inspiration begins before complete exhalation, leading to gas trapping and increased end-expiratory lung volume. *Exp.*, expiration; *FRC*, functional residual capacity; *Insp.*, inspiration; *Vtrapped*, volume of trapped gas above FRC. (From Levy BD, Kitch B, Fanta CH. Medical and ventilatory management of status asthmaticus. Intensive Care Med. 1998;24:105-117.)

During a severe attack, inspiratory transpulmonary pressures in excess of 50 cm H_2O may be generated, compared with approximately 5 cm H_2O during normal breathing.[48] The increased muscle work is accompanied by an increase in blood flow to the diaphragm, but this flow often is insufficient to meet the much greater metabolic demands.[49] Failure to promptly relieve the airway obstruction and reduce the work of breathing eventually leads to respiratory muscle fatigue, inadequate ventilation, and respiratory failure.

States of advanced airway obstruction and dynamic hyperinflation typical of severe asthma attacks have a significant impact on the circulatory system. The highly negative intrapleural pressures generated by spontaneously breathing patients during inspiration favor transcapillary fluid movement into the interstitium and air spaces, promoting pulmonary edema.[47] They also cause a phasic increase in left ventricular afterload and a decrease in cardiac output[50] that is clinically manifested as pulsus paradoxus.[51] Right ventricular afterload may be increased during severe asthma as a result of pulmonary vasoconstriction related to hypoxia and acidosis. A state of increased pulmonary vascular resistance resulting from dynamic hyperinflation also can increase right ventricular afterload, further affecting cardiac output.[51-53]

Clinical Assessment

History

The child with an asthma exacerbation usually presents with complaints of difficulty breathing and shortness of breath. The presence of these complaints in a child known to have had previous asthma exacerbations is highly suggestive of the diagnosis. A significant percentage of children have a history of a coexisting viral upper respiratory infection, whereas some describe exposure to known allergic triggers. Circumstances permitting, time should be taken to inquire about the presence of high-risk factors (discussed earlier) for severe disease and the adequacy of maintenance therapy.

Physical Examination

Children with severe forms of acute asthma commonly present with tachypnea, diaphoresis, increased use of accessory muscles, and nasal flaring. Sick nonverbal children may appear anxious, agitated, or simply unable to be distracted from the task of breathing. Older children often assume a tripod sitting position and may voice a sensation of impending doom. Speech occurs in short phrases because of the rapid respiratory rate. The presence of intercostal, subcostal, and suprasternal retractions; nasal flaring; the inability to speak in sentences; and agitation are signs

of impending respiratory failure. Evolution or persistence of these signs is followed by slower labored breathing, confusion or obtundation, and respiratory arrest.

Wheezing, which is a common clinical finding in patients with acute asthma exacerbations, is the audible manifestation of the transmitted turbulence to airflow in the intrathoracic intrapulmonary airways. Wheezing is usually expiratory as a result of the dynamic compression of conducting airways, but it can be inspiratory as well. Wheezing in persons with severe asthma usually is bilateral. Asymmetrical wheezing suggests regional mucous plugging, atelectasis, pneumothorax, or the presence of a foreign body. The degree of wheezing correlates poorly with disease severity,[54] because wheezes are heard only in the presence of sufficient airflow. A patient with severe airway obstruction and limited airflow may have a silent chest upon initial examination, but loud wheezes may develop after effective therapy is instituted. Likewise, in a patient with loud wheezes who continues to worsen, a reduction in wheezing may occur as a prelude to respiratory failure.

An objective assessment of disease severity is important in evaluating a patient's response to therapy. Several asthma severity scores are widely used in clinical practice, including the Clinical Asthma Score (CAS), the Pediatric Asthma Severity Score (PASS), and the Preschool Respiratory Assessment Measure (PRAM).[55-57] Wood and colleagues[58] developed a practical clinical asthma score specifically intended to identify near-fatal asthma. It is composed of five variables with three different grades that allows for semiquantitative assessment of disease severity (Table 53.1), and it correlates well with the need for prolonged bronchodilator therapy and hospitalization.[59] Increasing scores correlate with progressive hypercarbia, and scores >5 often indicate respiratory failure. However, although clinical asthma scores seem to be useful for assessing the severity of an attack, they are not as effective in prospectively identifying patients who require prolonged hospitalization or in whom complications and subsequent disability develop.[60,61] There is still a need for a single scoring system with sufficient validity, reliability, and utility for universal clinical application.[62]

TABLE 53.1

Clinical Asthma Evaluation Score*

	0	1	2
PaO_2 (torr) *or*	70-100 in 21% O_2	<70 in 21% O_2	<70 in 40% O_2
Cyanosis	None	In 21% O_2	In 40% O_2
Inspiratory breath sounds	Normal	Unequal	Decreased to absent
Accessory muscles used	None	Moderate	Maximal
Expiratory wheezing	None	Moderate	Marked
Cerebral function	Normal	Depressed or agitated	Coma

*A score of 5 or more is thought to be indicative of impending respiratory failure. A score of 7 or more with $PaCO_2$ >65 torr indicates existing respiratory failure.

Data from Wood DW, Downes JJ, Lecks HI. A clinical scoring system for the diagnosis of respiratory failure. Preliminary report on childhood status asthmaticus. Am J Dis Child. 1972;123:227-228.

A less frequently used but more objective method of assessing disease severity and progression in patients with severe asthma is measurement of the pulsus paradoxus. Originally described by Adolf Kussmaul[63] in a patient with constrictive pericarditis, pulsus paradoxus also is observed in conditions in which pleural

pressure swings are exaggerated, such as critical asthma. The simplest definition of pulsus paradoxus is an exaggeration of the physiologic inspiratory decrease in systolic blood pressure[64] (Fig. 53.3). Several mechanisms have been proposed for the occurrence of pulsus paradoxus in persons with asthma, and it is likely that various mechanisms contribute differently depending on the adequacy of intravascular volume, the magnitude of pleural pressure swings, the degree of pulmonary hyperinflation, and the state of cardiac contractility. These mechanisms include cyclic increases in left ventricular afterload and in venous return to the right heart[51] from highly negative intrapleural pressure during inspiration[65]; decreased left ventricular preload as a result of inspiratory blood pooling in the pulmonary vasculature[66]; impaired left ventricular diastolic filling caused by a leftward shift of the interventricular septum resulting from increased venous return to the right heart[67]; constraint of cardiac filling because of longitudinal inspiratory deformation of the pericardium[51]; and increased right ventricular afterload with decreased filling of the left ventricle as a result of hyperinflation, acidosis, and hypoxia.[68] The pulsus paradoxus can be measured easily in a patient who is spontaneously breathing by transducing pressure signals from an indwelling arterial catheter. Alternatively, it can be measured with a manual sphygmomanometer by inflating the cuff 20 mm Hg above the systolic pressure and then deflating it slowly until the first Korotkoff sounds are heard (systolic blood pressure). Initially, Korotkoff sounds are heard only during expiration. The cuff is then carefully deflated until the point where the sounds are appreciated during both inspiration and expiration and correspond to every heartbeat. The difference between the highest systolic pressure and the pressure at which all Korotkoff sounds are heard is the magnitude of the pulsus paradoxus. During normal breathing, this difference is less than 5 mm Hg, but it is generally greater than 10 mm Hg during acute asthma exacerbations and greater than 20 mm Hg in patients with more severe disease.[69] Changes in the magnitude of pulsus paradoxus during the course of therapy are good indicators of disease severity and clinical response to treatment.[51,69]

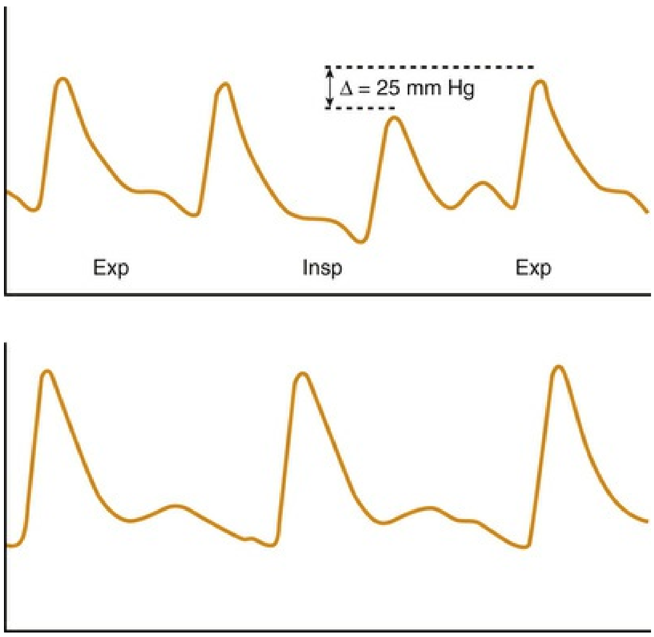

FIG. 53.3 Pressure recording from a radial artery catheter of a

spontaneously breathing patient with airway obstruction. *Upper panel:* Abnormally high pulsus paradoxus of 25 mm Hg is measured as the difference (Δ) in systolic blood pressure between expiration (Exp) and inspiration (Insp). *Lower panel:* Normal slight physiologic variation of the systolic blood pressure as a function of the respiratory cycle 12 hours after the onset of treatment.

In patients with severe asthma exacerbations, the liver is often palpable despite a normal liver span, a finding explained by caudal displacement of the liver by the diaphragm, flattened by the hyperinflated lungs.

Radiography

A chest radiograph is not routinely indicated in acute severe asthma[16] but may be useful in patients suspected of having a pneumothorax, pneumomediastinum, pneumonia, or clinically important atelectasis. In children presenting with a first episode of severe wheezing, a chest radiograph may help diagnose anatomic abnormalities (such as vascular rings or a right-sided aortic arch) or foreign bodies. We generally obtain a chest radiograph in patients who are sick enough to require monitoring and treatment in the ICU to exclude the possibility of unsuspected extrapulmonary or airspace disease.

Laboratory Data

Arterial Blood Gas Analysis

Arterial blood gas measurements provide objective information on the adequacy of ventilation and oxygenation of the patient with asthma. The typical blood gas abnormality in the early phase of acute asthma is hypoxemia with hypocapnia ($Pa{CO_2}$ <35 torr), reflecting hyperventilation.[70] With worsening airway obstruction, $Pa{CO_2}$ measurements return to the normal range of approximately 40 torr. However, this "normal" $Pa{CO_2}$ should not be viewed as reassuring when taken in the context of prolonged expiratory time, tachypnea, and accessory muscle use.[71] In fact, $Pa{CO_2}$ greater than 40 torr in a patient with a severe asthma exacerbation should be interpreted as a sign of evolving respiratory muscle fatigue and warrants close clinical observation. Sicker patients often exhibit a mixed respiratory and metabolic acidosis.[72] Lactic acidosis is frequently encountered in these patients and usually is secondary to excess sympathetic stimulation (type B lactic acidosis),[73] though it may also reflect tissue hypoxia and impending respiratory failure.[74] Measurement of the lactate: pyruvate ratio may help distinguish the etiology of lactic acidosis.

Abnormal arterial blood gas measurements alone should not be the basis for the decision of whether to intubate a child with asthma. This is dictated by the overall clinical status and may come before blood gas measurements reach the usual criteria for respiratory failure. In children requiring mechanical ventilation, frequent blood gas measurements are essential to monitor disease progression and the adequacy of ventilatory support. Additionally, blood gas analysis may be the only means to diagnose significant hypercarbia in critical asthma patients who have neurologic comorbidities or static encephalopathy.

Electrolytes and Complete Blood Cell Count

Routine blood chemistry analysis and blood cell counts generally are not helpful in patients with acute severe asthma. Children who present with a protracted asthma attack may have evidence of dehydration with elevated blood urea nitrogen or decreased bicarbonate as a result of inadequate oral fluid intake and increased insensible water losses. Patients undergoing repeated treatments with nebulized or intravenous (IV) β-agonist agents might show evidence of hypokalemia from the potassium shift to the intracellular space. The white blood cell count usually is normal, although some atopic patients may exhibit elevated eosinophil counts. The presence of leukocytosis does not necessarily indicate infection and often is related to adaptive stress or the administration of exogenous corticosteroids.

Muscle Enzymes

Myoglobin, a heme protein present in skeletal and cardiac muscle, is often elevated in patients with near-fatal asthma.[75] At least one-third of patients with acute severe asthma exhibit an elevated plasma creatine kinase (CK).[75] Although such elevations seem to be more pronounced in patients with marked acidemia or with more severe respiratory insufficiency, a convincing correlation between disease severity and CK elevation has not been established.[75] Though the CK-myocardial bound (CK-MB) isoenzyme is increased in some patients, most elevations in CK are not secondary to cardiac disease.[75] However, patients with acute severe asthma do have risk factors for acute cardiac injury, including hypoxemia, acidosis, and high myocardial energy demand. Troponin may be elevated even in patients without known cardiac disease. In one study, 36% of critical asthma patients without known cardiac disease (n = 64) who had troponin measured as part of clinical care had elevated levels,[76] and all eight cases of troponin >0.5ng/mL (range: 1–12.6 ng/mL) were associated with sustained diastolic hypotension. Diastolic hypotension develops in many children treated with continuous β-agonist medications, potentially decreasing coronary perfusion,[76] and should be observed for.

Electrocardiography

Patients with significant airway obstruction and hyperinflation may exhibit a change in the mean frontal P-wave vector. A P-wave axis greater than 60 degrees has been associated with hyperinflation in both pediatric and adult patients with airway obstruction and is thought to represent positional atrial changes caused by inferior displacement of the diaphragm.[77]

Twelve-lead electrocardiography and continuous cardiac monitoring are valuable tools in the care of patients with critical asthma in the ICU. These patients usually receive high doses of β-agonist drugs and may show evidence of hypokalemia (low-voltage T waves) or cardiac arrhythmias.[78,79] The already increased myocardial energy demand resulting from airway obstruction is compounded by the chronotropic and vasodilatory effects of β-agonist drugs and may lead to myocardial ischemia, particularly in adult patients with restricted coronary perfusion. Pediatric patients may exhibit electrocardiographic (ECG) and enzymatic evidence of myocardial ischemia, particularly during treatment with intravenously administered

isoproterenol.[80] However, despite the fact that a study reported that a high percentage (66%) of patients exhibited nonspecific ST segment changes or other criteria suggestive of ischemia, these changes were not well correlated with initiation of terbutaline therapy or elevations in cardiac troponin T.[81]

Spirometry

Measurement of peak expiratory flow rates can be used to estimate the degree of airway obstruction and response to therapy in patients presenting to the emergency department with an acute asthma attack. This is less useful in the ICU because sick patients with severe respiratory distress may be unable to perform an adequate forced expiratory maneuver. Measurements also may not be reliable in younger patients who are incapable of coordinating a rapid forced expiratory effort.

Treatment

Initial Management in the Emergency Department

Pediatric patients with mild acute asthma exacerbations generally are treated in the emergency department with one or more doses of an inhaled β-agonist, such as albuterol (salbutamol). Most of these patients also should receive a systemic corticosteroid, such as prednisone, and then can be sent home to complete a 3- to 5-day course of therapy. Patients with mild disease often respond well to initial treatment and do not require the attention of a pediatric intensivist.

Patients with moderate or severe acute asthma attacks require aggressive treatment from the outset. Because most patients with moderate or severe attacks have enough intrapulmonary shunt to result in hypoxemia, supplemental oxygen therapy should be initiated at the earliest time possible. The inspired oxygen can be adjusted once SpO_2 is measured and can be kept above 92%. It should be obvious that use of supplemental oxygen will cause an increase in SpO_2 but will have no impact on ventilation. Therefore one must not assume that ventilation is adequate in a patient with normal SpO_2 during administration of supplemental oxygen therapy.

Nebulized β-agonist agents, such as albuterol (salbutamol), are the most commonly used first-line therapy in the emergency department. The usual albuterol dose ranges between 0.05 and 0.15 mg/kg, diluted with 1 or 2 mL of normal saline solution. However, from a practical standpoint, patients weighing 20 kg or more usually are administered 5-mg doses, whereas patients weighing less than 20 kg receive 2.5-mg doses. Albuterol doses are repeated every 20 minutes during the first hour, with the need for additional doses dictated by clinical response.

Patients with moderate or severe acute asthma also should receive a dose of systemic corticosteroid in the emergency department, which usually is administered prior to the second dose of albuterol. Prednisone (2 mg/kg) can be administered orally and generally is well tolerated. Oral prednisone is superior to inhaled fluticasone in children with severe asthma as evidenced by greater improvement in pulmonary function and lower hospitalization rates.[82] Alternatively, dexamethasone administered as a single intramuscular dose (0.3–1.7 mg/kg) or enterally (0.6 mg/kg daily for 2 days) has been shown to be equivalent to 5-day courses of prednisone

with less emesis.[83] The role of corticosteroid drugs in reversing an acute asthma attack in the emergency department has been the subject of debate, considering that these drugs require at least 4 to 6 hours for peak effects to be manifested.[84] However, regardless of considerations about onset of action, acute suppression of inflammation is a cornerstone of acute asthma treatment, and there is evidence that early administration may reduce the rate of hospitalization.[85] Patients with more severe asthma exacerbations, those unable to tolerate oral medication because of respiratory distress or emesis, or those with a history of nausea during intensive β-agonist therapy should be given parenteral corticosteroid drugs such as methylprednisolone (2 mg/kg administered intravenously, followed by 0.5 to 1 mg/kg/dose administered intravenously every 6 hours).

Inhaled or nebulized anticholinergic agents such as ipratropium bromide are an important adjunct to the treatment of asthma exacerbations in the emergency department. In patients treated with one dose of a corticosteroid, use of ipratropium bromide (500 μg/2.5 mL) in conjunction with the second and third albuterol doses has been associated with greater clinical improvement[86] and reduced hospitalization rates compared with corticosteroid and albuterol alone.[87]

Magnesium sulfate administered as a single intravenous bolus (25–40 mg/kg over 20 minutes) has been shown to reduce hospitalization rates in children with moderate to severe asthma when administered in the emergency department.[88,89] In practice, magnesium sulfate is more commonly used as an adjunct in severe asthma to prevent respiratory failure and ICU admission.[90]

Admission Criteria

Most patients with an acute asthma exacerbation respond to treatment in the emergency department and are discharged home. Among patients whose symptoms persist despite initial treatment, most can safely be managed in the general pediatric inpatient ward. Indications for hospitalization after treatment in the emergency department are loosely defined but may include (1) an inadequate response to three or four aerosol treatments; (2) relapse within 1 hour of receiving treatment with aerosols and steroids; (3) persistent SpO_2 measurements of less than 91% in room air; (4) the need for oxygen therapy; (5) a significant reduction in peak expiratory flow rate, especially with a poor response to bronchodilators; (6) having unreliable family support or being unable to comply with outpatient treatment; and (7) multiple visits for the same episode.[91,92] Patients who require higher levels of monitoring, more invasive and aggressive treatment, or who deteriorate during hospitalization in the general pediatric ward should be admitted to the PICU.

Management in the Intensive Care Unit

General

Patients with critical asthma who are admitted to the ICU represent a heterogeneous group, thus requiring different levels of monitoring and treatment. However, all patients who are sick enough to warrant admission to the ICU should be monitored using continuous ECG tracing, continuous respiratory rate, noninvasive blood pressures, and SpO_2. Sicker patients who require frequent blood sampling will

benefit from an indwelling arterial catheter. Patients in respiratory failure requiring mechanical ventilation should have reliable and adequate central venous access.

Oxygen

Patients with more severe asthma exacerbations universally exhibit hypoxemia as a result of intrapulmonary shunts caused by mucous plugging, atelectasis, and hyperinflation. Treatment with β-agonist agents also contributes to hypoxemia by abolishing regional pulmonary hypoxic vasoconstriction and increasing intrapulmonary shunt.[93,94] Patients may have hypoxemia despite a normal-appearing chest radiograph, as regional hyperinflation may result in the conversion of lung segments from West zone 2 to zone 1, increasing ventilation-perfusion mismatch. Therefore humidified oxygen should be used for nebulization and continuously between treatments.[95] Supplemental oxygen can safely be incorporated into the treatment algorithm, because, unlike in some adult patients with severe chronic obstructive pulmonary disease[96] or asthma,[97] no evidence exists to suggest that supplemental oxygen suppresses the respiratory drive in children with critical asthma.

Fluids

Patients with critical asthma usually present with decreased total body water because of decreased oral fluid intake and increased insensible water losses. Therefore most patients require some degree of volume expansion. This should be carefully balanced with the need to avoid overhydration because of the propensity for transcapillary fluid migration and alveolar flooding exhibited by some patients with large swings in intrathoracic pressures. The need for rapid fluid expansion often becomes obvious shortly after intubation of patients with low intravascular volumes who are receiving β-agonist agents. Patients should remain NPO and on isotonic intravenous fluids until an improvement in respiratory status allows for the safe initiation of enteral nutrition.

Corticosteroids

Corticosteroids play a central role in the treatment of patients with critical and near-fatal asthma, considering that these conditions are predominantly inflammatory in nature. Glucocorticosteroid agents modulate airway inflammation by a number of mechanisms, including direct interaction with cytosolic receptors and glucocorticosteroid response elements in gene promoters and indirect effects on binding of transcription factors, such as nuclear factor–κB, and on other cell signaling processes, such as posttranscriptional events.[98] Gene products suppressed by glucocorticosteroid agents include a wide range of cytokines (IL-1, IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-8, IL-11, IL-12, IL-13, tumor necrosis factor-α, and granulocyte-macrophage colony-stimulating factor), adhesion molecules (intracellular adhesion molecule-1 and vascular cell adhesion molecule-1), and inducible enzymes, including NO synthase and cyclooxygenase-2.[99] Transcription of other genes, such as lipocortin-1 and the β_2-adrenergic receptor, may be enhanced.[99] Glucocorticosteroid agents also decrease airway mucus production, reduce inflammatory cell infiltration

and activation, and attenuate capillary permeability.[100-103]

In children with critical or near-fatal asthma, glucocorticosteroids should be administered by the IV route. The oral route may be used in selected cases, but inhaled glucocorticosteroids play no role in the treatment of the hospitalized patient.[30,82] The most common agent used in the United States is methylprednisolone because of its wide availability as an IV preparation and lack of mineralocorticoid effects. The usual dose of methylprednisolone is 0.5 to 1 mg/kg/dose, administered intravenously every 6 hours. Hydrocortisone, an agent with both glucocorticoid and mineralocorticoid activity, can be used as an alternative at doses of 2 to 4 mg/kg/dose, administered intravenously every 6 hours. Short courses of steroids usually are well tolerated without significant adverse effects.[102] However, hypertension, hyperglycemia, mood disorders, and serious viral infections, such as fatal varicella, have been reported in previously well patients with asthma who have received glucocorticosteroid drugs.[102,104,105] Duration of corticosteroid therapy is dictated by the severity of illness and clinical response, but airway inflammation continues long after the clinical symptoms improve. Once initiated, treatment with systemic corticosteroids is continued for 5 to 7 days and followed by long-term inhaled steroids. Longer treatment courses necessitate gradual weaning of the drug to decrease the chances of symptomatic adrenal insufficiency or relapse. Prophylaxis with an H_2 blocker or proton pump inhibitor should be considered because of the possibility of steroid-associated gastritis and gastric perforation.[106]

β-Agonists

The β-agonist properties of the sympathomimetic agents cause bronchial smooth muscle relaxation and, hence, bronchodilatation. These agents also can increase diaphragmatic contractility, enhance mucociliary clearance, and inhibit bronchospastic mediators from mast cells.[107] Therefore β-agonists, along with systemic corticosteroids, are the mainstay of pharmacotherapy in persons with critical and near-fatal asthma. β_2-receptor selectivity is desirable to avoid adverse effects of nonselective α- and β_1-adrenergic receptor stimulation. However, despite relative β_2 selectivity, cardiovascular adverse effects remain a dose-limiting factor. The relative potency of various agents for the β_2 receptor is as follows: isoproterenol > fenoterol > albuterol > terbutaline > isoetharine > metaproterenol.[108] Of these, only albuterol and terbutaline are widely used in clinical practice, with some centers still using isoproterenol in selected occasions.

Once bound to the β-adrenergic receptor, β-agonists activate adenyl cyclase, resulting in increased intracellular cyclic adenosine monophosphate (cAMP) levels, which leads to bronchial and vascular smooth muscle relaxation. Dose-response curves demonstrate that large dose increases fail to enhance bronchodilation significantly. However, as the degree of bronchial constriction increases, the bronchodilation dose-response curve shifts to the right, indicating the need for a higher dose to achieve the desired response.[108]

In persons with near-fatal asthma, parenteral and aerosol routes of administration are used exclusively. Traditional therapy for persons with critical asthma previously included subcutaneous doses of epinephrine, but epinephrine is no longer widely used because of the development of newer, more selective β-agonist agents with

longer durations of action and fewer adverse effects.

The most frequent adverse effects of β-agonist agents are skeletal muscle tremor, nausea, and tachycardia. These adverse effects are common to nonselective and selective β_2-agonist drugs administered either by IV or inhalational routes. Other cardiovascular adverse effects include blood pressure instability (predominantly diastolic hypotension) and cardiac dysrhythmias.[109,110] Myocardial ischemia has been well documented as a serious complication of IV (and inhalational) isoproterenol administration to children with critical asthma.[80,111] However, continuous IV infusions of terbutaline generally are safe and are not associated with significant cardiotoxicity.[81] Prolongation of the QTc interval and hypokalemia have been observed during IV infusions of β-agonist drugs.[112] Hypokalemia occurs even with a relatively stable total body potassium and is the result of intracellular potassium shifting resultant, at least in part, from an increased number of sodium-potassium pumps and not from augmented potassium elimination.[113] Therefore supraphysiologic potassium supplementation is rarely necessary. A significant adverse effect of β-agonist agents is hypoxemia. This is related to drug-mediated pulmonary vasodilation overcoming local hypoxic vasoconstriction and increasing perfusion to poorly ventilated lung units and intrapulmonary shunt.[93,94]

Albuterol (Salbutamol)

Albuterol is the most β_2-specific aerosol agent available in the United States. It usually is administered every 20 minutes during the initial phase of treatment at a dose of 0.05 to 0.15 mg/kg. The optimal dose and frequency of albuterol are variable and affected by spontaneous tidal volume, breathing pattern, device, and technique. On average less than 1% of the nebulized drug is deposited in the lung.[114] After the initial series of three albuterol treatments, continuous albuterol nebulization should be started for patients who require nebulization treatments more frequently than every hour.

Continuous albuterol nebulization appears to be superior to repeated intermittent dosing and does not cause significant cardiotoxicity.[115-117] A small prospective randomized study in children with critical asthma and impending respiratory failure indicated that children treated with continuous albuterol nebulization had more rapid clinical improvement and shorter hospitalizations than children treated with intermittent albuterol doses.[116] Continuous administration of albuterol also was associated with more efficient allocation of respiratory therapists' time[116] and could offer the added advantage of more hours of uninterrupted sleep to patients who often are already exhausted.[118] The usual dose of continuously administered albuterol ranges between 0.15 and 0.45 mg/kg/h, with a maximum dose of 20 mg/h. Higher doses of albuterol have been used in patients who are unresponsive to standard treatment.[119] However, we do not support this practice, because the intensification of adverse effects usually outweighs any small incremental gain in bronchodilatation. It should be remembered that a major component of bronchial obstruction in severe asthma is from airway wall edema and mucus obstruction of the airways, neither of which is responsive to bronchodilators.

Albuterol is a 50 : 50 mixture of R-albuterol (levalbuterol), the active enantiomer that causes bronchodilation, and S-albuterol, which was thought to be inactive in humans. Levalbuterol, the pure R-isomer, is approved for use in the United States as

a preservative-free nebulizer solution. The purported advantage levalbuterol over albuterol stems from the fact that S-albuterol may not be completely inert and has a longer elimination half-life than R-albuterol.[120,121] However, the notion that S-albuterol is not inert and that it is capable of clinically significant adverse effects is not universally accepted.[122-124] A large randomized controlled trial of levalbuterol versus racemic albuterol in children with asthma demonstrated a decreased rate of hospitalization in patients treated with levalbuterol.[125] However, this study had methodological problems, as the primary outcome variable (rate of hospital admission) was left to the discretion of the treating physicians and none of the secondary outcome variables were significantly different between treatment groups once the patients had been admitted to the hospital.[125] More recent randomized clinical studies in children with asthma failed to show that levalbuterol is superior to racemic albuterol.[126-128] Furthermore, although the cost of levalbuterol has decreased significantly, this drug continues to be more expensive than albuterol (M.L. Biros, PharmD, Rainbow Babies & Children's Hospital, personal communication, 2015). Considering the lower cost of albuterol and the paucity of clinical evidence supporting the superiority of levalbuterol, we favor albuterol as the routine bronchodilator of choice in children with critical and near-fatal asthma.

Intravenously administered albuterol is not available in the United States. However, the efficacy of albuterol infusions in patients with severe asthma has been well established in countries where the IV preparation is available.[129,130]

Terbutaline

Terbutaline is a relatively selective β_2-agonist with a mechanism of action similar to that of albuterol. It is the most commonly used parenteral β-agonist in the United States and is available for nebulization, subcutaneous injection, and IV use. Because of its lower β_1-receptor affinity, subcutaneous administration of terbutaline has largely supplanted the use of epinephrine in persons with severe acute asthma. Subcutaneous terbutaline is rarely used in the PICU; it is reserved for patients with acute worsening of the respiratory status who do not have vascular access and in whom access cannot be easily obtained. Subcutaneous terbutaline is more commonly used in the acute management of sick patients in the emergency department and before hospital contact. The usual subcutaneous terbutaline dose is 0.01 mg/kg/dose (maximum 0.25 mg) subcutaneously every 20 minutes for three doses, as necessary.

Terbutaline is more commonly used in the ICU by IV infusion. This therapy is indicated for patients with critical asthma who fail to improve or who show signs of deterioration during treatment with nebulized β_2-agonists, ipratropium bromide, and steroids. The usual range of IV terbutaline dosage is 0.1 to 10 μg/kg/min, as a continuous infusion prepared in 0.9% normal saline solution or D_5W.[109] In our clinical experience, however, most patients are started on a dose of 1 μg/kg/min and the dose is titrated to effect, with doses higher than 4 μg/kg/min rarely necessary. Patients starting therapy at doses lower than 1 μg/kg/min can be given a loading dose of 10 μg/kg over 10 minutes to accelerate the onset of action.

Anticholinergic Agents

Anticholinergic agents have become an important part of the treatment of children

with severe acute asthma. The typical anticholinergic agent used in treating patients with asthma is ipratropium bromide, a quaternary ammonium compound formed by the introduction of an isopropyl group to the N atom of atropine. Unlike atropine (a tertiary ammonium compound), ipratropium bromide does not cross the blood-brain barrier and does not cause central anticholinergic adverse effects. Considering that bronchial smooth muscle tone is influenced by the parasympathetic input, ipratropium bromide can produce bronchodilation by inhibition of cholinergic-mediated bronchospasm.[131] An important property of ipratropium bromide is the lack of negative effect on ciliary bronchial epithelium, unlike the marked inhibition of ciliary beating and mucociliary clearance produced by atropine.[131]

Nebulized ipratropium bromide (250- to 500-μg doses) can be used every 20 minutes during the first hour in the emergency department. The recommended dose for continuation therapy is 250 to 500 μg, given every 6 hours. After inhalation, peak responses usually develop over 30 to 90 minutes, and clinical effects may persist for more than 4 hours.[131] Systemic effects are minimal because less than 1% of an inhaled dose of ipratropium bromide is absorbed into the circulation. However, extrapulmonary effects such as mydriasis and blurred vision have been reported as a result of inadvertent topical ocular absorption of the drug.[132,133]

The addition of ipratropium bromide to nebulized albuterol in the treatment of bronchospasm makes pharmacologic sense, because albuterol causes bronchodilatation by increasing cAMP levels, whereas the effect of ipratropium bromide is mediated by a decrease in cyclic guanosine monophosphate. The combined use of ipratropium bromide and nebulized albuterol in treating children with asthma who present to the emergency department has proved to be cost effective and reduces the rate of admission to the hospital.[86,87] However, the routine addition of repeated doses of nebulized ipratropium bromide to a standard regimen of β_2-agonist agents and systemic steroid drugs in hospitalized children with asthma does not appear to confer a significant benefit.[134,135] Considering the high safety profile of inhaled ipratropium bromide treatments and the benefits of its use in the emergency department, we find it reasonable to administer ipratropium bromide along with standard therapy for critically ill patients with asthma despite the lack of robust data specific to the PICU population.

Magnesium Sulfate

Magnesium is a physiologic calcium antagonist that inhibits calcium uptake and relaxes bronchial smooth muscle. It has been known since the 1940s that magnesium causes bronchorelaxation in patients with asthma,[136] but its use as an adjunct in treating patients with severe asthma has occurred only recently. Numerous reports, case series, and randomized controlled trials have suggested clinical improvement when asthmatic patients receive IV magnesium sulfate infusions in the emergency department or ICU.[137,138] Although there is some evidence that magnesium is as effective as albuterol when delivered by nebulization[139] and has been used successfully as a liquid vehicle for albuterol nebulization,[140] a larger trial failed to show a significant benefit on hospital length of stay.[141]

The indication for IV magnesium sulfate in children with critical or near-fatal asthma is still unclear because of the paucity of randomized controlled trials. Some studies suggest that magnesium sulfate infusions are associated with significant

improvements in short-term pulmonary function,[88,142,143] whereas another study failed to show improvement in disease severity or a reduction in hospitalization rates.[89] The usual dose of magnesium sulfate in children with critical or near-fatal asthma is 25 to 40 mg/kg/dose, infused intravenously, over 20 to 30 minutes.[144] The onset of clinical response is rapid (occurring in minutes) and generally is observed during the initial infusion. Patients should be carefully monitored for adverse effects during the infusion, which include hypotension, nausea, and flushing. Serious toxicity—such as cardiac arrhythmias, muscle weakness, areflexia, and respiratory depression—is not a significant concern with the use of magnesium sulfate in persons with acute asthma, when used as directed. The IV infusion of magnesium sulfate under controlled conditions appears to be safe, and a subset of patients with critical and near-fatal asthma clearly responds to this therapy, which may reduce need for mechanical ventilator support.[88,142-145] A systematic review of the published randomized controlled trials supports the use of magnesium sulfate in addition to β_2-agonist agents and systemic steroid drugs in the treatment of persons with acute severe asthma.[146]

Methylxanthine Agents

Methylxanthine agents, as the name implies, are substances formed by the methylation of xanthine and include caffeine, theobromine, and theophylline. The water solubility of methylxanthine agents is very low but can be greatly enhanced by formation of complexes with a variety of compounds. Most notably, the combination of theophylline and ethylenediamine yields aminophylline, a water-soluble salt. A large number of methylxanthine derivatives have been developed, but only theophylline and aminophylline are relevant to the treatment of patients with asthma.

The exact molecular mechanism of theophylline-mediated bronchodilation is unclear but is thought to involve its action as a phosphodiesterase-4 inhibitor, reducing the degradation of cAMP, which in turn mediates cellular responses that result in bronchial smooth muscle relaxation.[147] Other mechanisms of action have been proposed, including inhibition of phosphoinositide 3-kinase activity,[148] adenosine receptor antagonism,[149] increasing histone deacetylase activity, stimulation of endogenous catecholamine release,[150] prostaglandin antagonism,[151] and alterations in intracellular calcium mobilization.[152] Theophylline is also known to cause inhibition of afferent neuronal activity,[153] thereby leading to inhibition of bronchospasm mediated by reflex activation of cholinergic pathways. Theophylline has antiinflammatory and immunomodulatory actions[154] and is known to augment diaphragmatic contractility and increase respiratory drive.[155]

In isolated human bronchial preparations in vitro theophylline concentrations greater than 70 μmol/L can induce a 50% reversal of bronchoconstriction.[156] Such high local concentrations presumably would be achieved with plasma levels greater than 10 to 20 μg/mL.[157] In clinical practice, however, this range poses a difficult problem because of the narrow window between therapeutic levels and toxicity, which often overlap. The half-life of theophylline ranges from 3 to 7 hours.[158] Therefore aminophylline, which is equivalent to 80% theophylline, generally is administered as a continuous IV infusion to avoid significant fluctuations in serum concentrations. When a decision is made to initiate therapy with theophylline or

aminophylline, a loading dose is given to achieve serum levels between 10 and 20 μg/mL. Assuming a normal average volume of distribution, a 1-mg/kg dose of theophylline (1.25 mg/kg of aminophylline) raises the serum concentration by 2 μg/mL. The loading dose should be administered over 20 minutes and should be followed immediately by the continuous infusion of the drug. Empiric doses of aminophylline can be started for patients with normal hepatic and cardiac function as follows: infants younger than 6 months: 0.5 mg/kg/h; infants aged 6 months to 1 year: 0.85 to 1 mg/kg/h; children aged 1 to 9 years: 1 mg/kg/h; and children older than 9 years: 0.75 mg/kg/h. Patients with compromised hepatic or cardiovascular function should be started at a dose of 0.25 mg/kg/h. Obese patients should have doses calculated on ideal body weight to prevent toxicity. Serum drug levels should be monitored 30 to 60 minutes after the loading dose and frequently during the continuous infusion, considering that steady-state concentrations are not achieved until approximately five half-lives, which corresponds to 24 to 36 hours of infusion.

A number of studies in adults and children with acute asthma indicate that therapy with theophylline or aminophylline is of no clinical benefit.[159-161] More recently, randomized, placebo-controlled trials tested the efficacy of aminophylline[18] and theophylline[162] in children with critical asthma. Aminophylline treatment resulted in significantly improved physiologic outcomes, such as oxygenation and pulmonary function testing, but did not decrease ICU length of stay and was associated with adverse effects such as nausea and vomiting.[18] Theophylline was associated with faster clinical improvement, but it had no effect on PICU length of stay and led to a significantly higher frequency of vomiting compared with control subjects.[162]

Considering the narrow therapeutic window (10 to 20 μg/mL), which often overlaps the toxicity (>15 μg/mL), the questionable evidence of clinical efficacy, and that methylxanthine agents have been associated with adverse effects ranging from nausea, vomiting, and fever to dyskinesias, seizures, and death, use of these agents has decreased significantly. In fact, methylxanthines were used in less than 6% of children with critical and near-fatal asthma admitted to pediatric ICUs in a multicenter study in the United States.[16] With these considerations in mind, we use methylxanthine agents only in occasional selected patients who fail to respond to maximal therapy with β-agonist agents, steroids, anticholinergic drugs, magnesium sulfate, and other adjuncts.

Helium-Oxygen Mixtures

Helium is a biologically inert gas that is less dense than any gas except hydrogen and is about one-seventh as dense as air. The medicinal application of helium and oxygen mixtures (heliox) in the treatment of asthma and extrathoracic airway obstruction has been known for nearly 8 decades.[163] Because of its low density, heliox reduces the Reynolds number. This effect is associated with a reduced likelihood of turbulent gas flow while facilitating laminar gas flow in the airways, thus decreasing the work of breathing in situations associated with high airway resistance.[164] Heliox provides a theoretic benefit in patients with obstructive lesions of the extrathoracic and intrathoracic airways. Several reports advocate the benefit of heliox in the management of children with extrathoracic airway obstruction.[164,165] The role of heliox in patients with asthma is less clear.

Research using heliox mixtures has demonstrated a greater percentage of lung particle retention and a greater delivery of albuterol from both metered-dose inhalers and nebulizers,[166,167] suggesting that one of the beneficial effects of heliox use in patients with asthma is improved deposition of aerosolized drugs. Although there is some evidence that 70%/30% heliox-driven continuous nebulized albuterol treatments are associated with a greater degree of clinical improvement compared with oxygen-driven continuous nebulized albuterol in children with moderate to severe asthma exacerbations,[166] other studies have shown no significant improvement in hospital or ICU length of stay.[168] The higher the needed FIO2, the less effective the heliox mixture.

Heliox has been recommended by some investigators as a useful adjunct in adult patients with severe asthma, both during spontaneous breathing and during mechanical ventilation.[169-172] Anecdotal reports suggest that heliox is associated with improvement in pulmonary function in children with acute asthma.[173,174] However, a small randomized crossover trial of heliox in spontaneously breathing patients with severe asthma failed to show improvement in pulmonary function or dyspnea scores.[175] Additionally, a systematic review of seven prospective, controlled trials in children and adults did not support the use of heliox in patients with moderate or severe acute asthma.[176] The paucity of well-executed, randomized, controlled studies makes it impossible to assess the therapeutic effect of heliox in children with asthma. In addition, should heliox be beneficial in some patients, the duration of administration and optimal helium-oxygen mixture remain undetermined. Until more sound information emerges, heliox remains an unproved therapy for pediatric asthma, and its use should be restricted to individual attempts in selected patients with severe refractory critical or near-fatal asthma who do not respond to conventional treatment.[177] To get full benefit from the lower gas density, 80 : 20 or 70 : 30 helium-oxygen mixtures must be used, limiting the therapy to those with low inspired oxygen needs.

Ketamine

Ketamine hydrochloride is a dissociative anesthetic agent with bronchodilatory properties that is available in a solution for IV or intramuscular administration. After IV administration, a sensation of dissociation is generally experienced within 15 seconds, followed by unconsciousness after another 30 seconds. This reaction is followed by profound analgesia that lasts 40 to 60 minutes and amnesia that may persist for 2 hours. Some patients, particularly older children, may experience a postanesthesia emergence reaction with confusion, agitation, and hallucinations. Usual ketamine doses do not significantly affect hypoxic or hypercarbic respiratory drive. Pharyngeal and laryngeal reflexes are maintained, and although the cough reflex is somewhat depressed, airway obstruction does not normally occur. Aside from its anesthetic properties, ketamine causes sialorrhea and increases airway secretions, cardiac output, heart rate, blood pressure, metabolic rate, cerebral blood flow, and intracranial pressure.[178] Pulmonary vascular resistance is not altered, and hypoxic pulmonary vasoconstriction is preserved. Ketamine inhibits bronchospasm and lowers airway resistance, presumably through blockage of *N*-methyl-D-aspartate receptors in airway smooth muscle.[179] The bronchodilatory effect of ketamine makes it an attractive agent in patients with asthma who require sedation and anesthesia

for intubation or mechanical ventilation.[180,181] However, the bronchodilatory effects of ketamine may be counteracted by the observed increase in airway secretions and sialorrhea.

Questions exist regarding the use of ketamine in nonintubated patients with critical asthma. In the emergency department, ketamine infusion added to standard therapy of nonintubated patients has not shown a clinical benefit.[182] However, limited evidence suggests that this therapy may be helpful in selected patients when trying to avoid the need for mechanical ventilation.[183] In our experience, the administration of ketamine to nonintubated children with critical asthma frequently precedes the need to intubate and is rarely associated with significant and noticeable clinical improvement. For this reason, attempts at administering ketamine to nonintubated children with severe critical asthma should always take place in the ICU under strictly monitored conditions and with personnel capable of rapidly establishing an airway for initiation of ventilatory support.

Ketamine usually is administered as an IV bolus of 2 mg/kg, followed by a continuous infusion of 1 to 2 mg/kg/h. The resulting sialorrhea and increased airway secretions can be attenuated by administration of glycopyrrolate or atropine. The concurrent use of benzodiazepines may attenuate the agitation and hallucinations in patients who experience emergence reactions following ketamine anesthesia.

Mechanical Ventilation

Indications

Only a small minority of patients with near-fatal asthma admitted to the PICU (10% to 12%) will require endotracheal intubation and mechanical ventilation.[16] The indications for intubation are not precisely defined, and the decision to proceed with intubation is largely based on clinical judgment. Absolute indications are obvious and include cardiac or respiratory arrest, profound hypoxemia refractory to supplemental oxygen administration, and respiratory failure. The decision to intubate should not be based solely on blood gas results. However, the presence of a mixed respiratory and metabolic acidosis, persistent hypoxemia, and agitation or obtundation, despite maximal therapeutic efforts, indicate impending respiratory arrest and signal the urgent need to proceed with intubation and mechanical ventilation.

Some patients may benefit from attempts to attenuate respiratory muscle fatigue with a trial of noninvasive ventilation.[184,185] However, the use of bilevel positive airway pressure requires patient cooperation and a well-sealed mask, which may prove difficult, if not impossible, to achieve in an anxious and agitated child with impending respiratory failure.

Intubation

The intubation of patients with near-fatal asthma is complicated by the fact that these patients are, by definition, fatigued, acidotic, and often also hypoxemic or agitated. Once the decision to intubate is reached, someone skilled and experienced in rapid sequence intubation should promptly perform the procedure. Intubation should be preceded by the administration of an anesthetic, such as an opiate,

propofol, or ketamine; a benzodiazepine; and a neuromuscular blocker. Ketamine is the preferred anesthetic because of its properties as a bronchodilator. Our practice is to use ketamine with a benzodiazepine, such as midazolam or lorazepam, to ensure adequate sedation and reduce the risk of hallucinations during emergence from anesthesia. Propofol may cause bronchodilatation and could be used as an alternative to ketamine, although this drug currently is not approved in the United States for continued use for anesthesia in the PICU after induction. Among the opiates, fentanyl is a widely available choice; morphine should be avoided because it is associated with histamine release and could, at least in theory, contribute to the allergic and inflammatory process. A rapid-acting neuromuscular blocker such as succinylcholine can be used to induce chemical paralysis. More commonly, a nondepolarizing neuromuscular blocker such as vecuronium, rocuronium, or cisatracurium is used. The patient should be preoxygenated with 100% oxygen by facemask during spontaneous breathing. Assisted breathing with a bag-mask apparatus can be performed with care taken to avoid worsening of dynamic hyperinflation and gastric distension. Whenever possible, a nasogastric tube should be placed in advance to decompress the stomach.

A cuffed endotracheal tube should be introduced and its placement confirmed by a colorimetric method or capnography, auscultation, and chest radiograph. Special attention to the manual ventilation technique is needed to avoid fast rates that often are inadvertently applied immediately following intubation. Rapid respiratory rates applied to intubated children with severe airway obstruction lead to iatrogenic hyperinflation, hypoxemia, and hemodynamic instability (hypotension). These patients require slow respiratory rates with prolonged expiratory times to allow for adequate gas exchange and lung volumes. A helpful technique is to use a stethoscope to auscultate for the disappearance of expiratory wheezes, prior to starting the next inspiration. The occurrence of desaturation and hypotension following intubation should prompt an equipment check and confirmation of tube placement. A tension pneumothorax must be considered in patients with hypoxemia and hypotension who fail to improve rapidly after administration of fluids and optimization of ventilation (or brief endotracheal tube disconnection), particularly when unequal breath sounds are present.

Ventilator Settings

The goal of mechanical ventilation in patients with near-fatal asthma is to reverse hypoxemia (if present), relieve respiratory muscle fatigue, and maintain a level of alveolar ventilation compatible with an acceptable pH, while avoiding iatrogenic hyperinflation and levels of intrathoracic pressure that reduce cardiac output. Therefore the choice of mechanical ventilator settings must take into consideration the significant derangements of lung mechanics and function that are inherent in persons with severe acute asthma. Ill-advised attempts to achieve a normal $PaCO_2$ would require fast respiratory rates, high minute volumes, and very high airway pressures, which are associated with the development of air leak (pneumothorax and pneumomediastinum) and high mortality rates.[186-188]

A paradigm shift in the ventilatory management of patients with asthma occurred with the introduction of a strategy of controlled hypoventilation reported by Darioli and Perret.[187] Their strategy resulted in no mortality in 34 episodes of mechanical

ventilation in 26 patients and significantly lower complication rates in comparison with historical controls.[187] This approach used tidal volumes between 8 and 12 mL/kg and targeted peak airway pressures up to 50 cm H_2O. Tidal volumes were reduced if the peak pressure limit could not be respected and higher $Paco_2$ measurements were tolerated.[187] A similar approach using respiratory rates lower than 12 breaths/min, tidal volumes between 8 and 12 mL/kg, peak inspiratory pressures of 40 to 45 cm H_2O, and permissive hypercapnia also resulted in few complications and no mortality or long-term morbidity in 19 mechanically ventilated children with near-fatal asthma.[186]

The modes of ventilatory support for patients with severe acute asthma can be divided between pressure and volume preset. No definitive evidence exists to suggest that one mode of ventilation is superior to the other. However, to safely ventilate a patient with asthma, the characteristics of each mode must be understood. Pressure control modes use a decelerating gas flow and have the advantage of ensuring that a particular inspiratory pressure limit is respected. The main disadvantage of pressure control modes is that tidal volumes can vary greatly with changes in airway resistance and pulmonary compliance. Volume control modes deliver a constant tidal volume, provided there is no significant air leak around the endotracheal tube. An added advantage of volume control is that it allows for comparison of peak inspiratory pressure and plateau pressure measurements (peak-to-plateau pressure), which can serve as a longitudinal indicator of airway resistance and response to therapy. For these measurements, the plateau pressure is obtained by performing an inspiratory hold (a feature available on most ventilators) and is then compared with the peak inspiratory pressure (Fig. 53.4). An increasing peak-to-plateau pressure indicates increasing airway resistance, whereas a decreasing peak-to-plateau pressure suggests response to therapy. A disadvantage of volume control ventilation is that very high lung volumes can develop if exhalation is incomplete, because tidal volumes remain constant breath to breath. The option of using pressure-regulated volume control, a mode available on several ventilators, offers some of the advantages of pressure control and of volume control, including optimal decelerating inspiratory gas flow, assured tidal volumes, and minimized airway pressures.

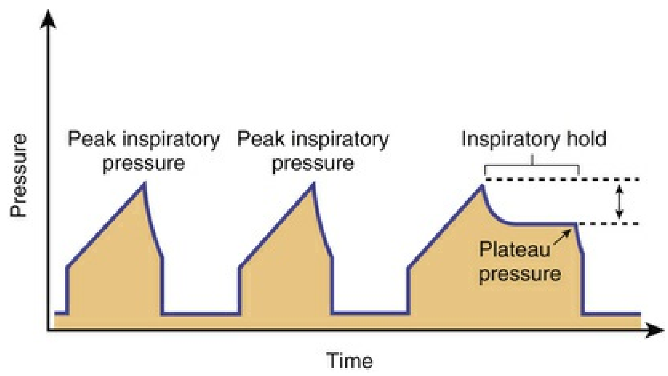

FIG. 53.4 Schematic representation of the airway pressure waveform over time during volume control ventilation. The peak-to-plateau pressure difference *(double-headed arrow)* is obtained after an inspiratory hold by comparing the peak pressure and the measured plateau pressure.

Use of positive end-expiratory pressure (PEEP) in intubated patients with asthma has been the focus of controversy. Externally applied PEEP may benefit patients with expiratory flow limitation resulting from dynamic compression of small airways by moving the equal pressure point further down the airway and enabling decompression of upstream alveoli.[189] The application of low levels of PEEP that are, by definition, lower than the level of auto-PEEP also may relieve dyspnea by facilitating ventilator triggering and synchronization for intubated patients capable of drawing spontaneous breaths.[189,190] However, as elegantly demonstrated by Tuxen,[191] the use of PEEP in chemically paralyzed patients with severe airflow obstruction is uniformly associated with higher lung volumes, increased airway and intrathoracic pressures, and circulatory compromise (Fig. 53.5).

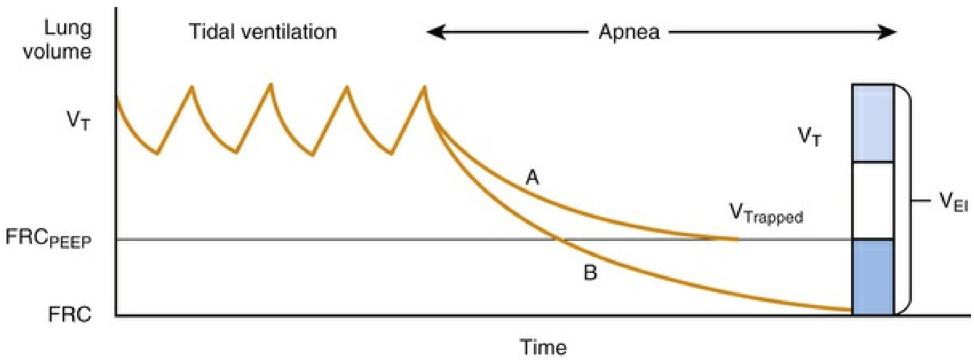

FIG. 53.5 Schematic representation of the measurement of V_{EI} both on and off PEEP by a period of apnea during steady-state ventilation. (A)V_{EI} measured with PEEP left on. (B) V_{EI} measured with PEEP turned off. *FRC*, functional residual capacity; *FRC_{PEEP}*, functional residual capacity resulting from PEEP; *PEEP*, positive end-expiratory pressure; *V_{EI}*, end-inspiratory lung volume above FRC; *V_T*, tidal volume; *$V_{Trapped}$*, volume of trapped gas above FRC. (From Tuxen DV. Detrimental effects of positive end-expiratory pressure during controlled mechanical ventilation of patients with severe airflow obstruction. Am Rev Respir Dis. 1989;140:5-9.)

Our preference is to use the volume control synchronized mandatory ventilation mode or the pressure-regulated volume control mode, with tidal volumes of 8 to 12 mL/kg, which can be reduced as needed to generate peak inspiratory pressures of 45 cm H_2O or less and plateau pressures 30 cm H_2O or less. The initial tidal volume target of 8 to 12 mL/kg might seem high, particularly in the era of lung protective ventilation with reduced tidal volumes for patients with acute respiratory distress syndrome. However, it is important to note that the typical patient with near-fatal asthma does not have significant parenchymal lung injury or the heterogeneously decreased lung compliance characteristic of patients with acute respiratory distress syndrome. Furthermore, once clinical stability is achieved, tidal volumes can often be reduced to achieve conservative peak and plateau pressure goals, as previously discussed. Respiratory rate is initially set between 6 and 12 breaths/min, and inspiratory time is set between 1 and 1.5 seconds, allowing for expiratory times between 4 and 9 seconds. PEEP is set at zero for the patient under neuromuscular blockade. With intensification of therapy and clinical improvement, neuromuscular blockade is stopped and trigger sensitivity for spontaneous breaths is optimized.

Once the patient no longer requires neuromuscular blockade, a low level of PEEP (lower than the measured auto-PEEP and generally not in excess of 8 cm H_2O) is applied to facilitate synchronization between the ventilator and the patient capable of triggering a breath. The resultant spontaneous breaths should be assisted by the application of pressure support. To be clear: The use of PEEP *should be avoided* in the patient with near-fatal asthma without significant parenchymal lung disease under neuromuscular blockade, as any applied expiratory pressure will translate into a proportional increase in hyperinflation. PEEP *should be applied* to the spontaneously breathing intubated patient, as it shifts the equal-pressure point distally, decreases inspiratory intrathoracic pressure swings, and facilitates ventilator trigger and synchrony.

Use of a ventilation strategy consisting of pressure support with PEEP has gained acceptance in the management of spontaneously breathing intubated patients with asthma, with the goal of reducing inspiratory work.[192] In fact, pressure support with PEEP was the most commonly used strategy (36% of patients) in a study of 261 patients with fatal and near-fatal asthma.[7] In this strategy, PEEP is used to facilitate ventilator triggering by narrowing the gap between proximal and distal airway pressures during a hyperinflated obstructed state. Pressure support is then applied to facilitate inspiration while reducing associated work of breathing. The patient initiates and terminates every breath and dictates the inspiratory time, respiratory rate, and depth of each breath, making this a comfortable mode for the patient with some degree of awareness.

Ventilatory Monitoring

Regardless of the chosen mode of ventilation, patients with near-fatal asthma undergoing mechanical ventilation require close monitoring. Frequent auscultation provides valuable information regarding symmetry of breath sounds (assessing for pneumothorax or mucous plugging) and optimal length of exhalation. Monitoring modules capable of analyzing and displaying permutations of important variables, such as pressure, volume, flow, and time, can provide important information that assists in the optimization of ventilator settings (Fig. 53.6). Monitoring the peak-to-plateau pressure difference allows for inferences regarding airway resistance and response to treatment. The shape of the capnography curve also may provide insights regarding adequacy of lung emptying (Fig. 53.7), whereas integrated volumetric capnography can track changes in alveolar dead space over time.

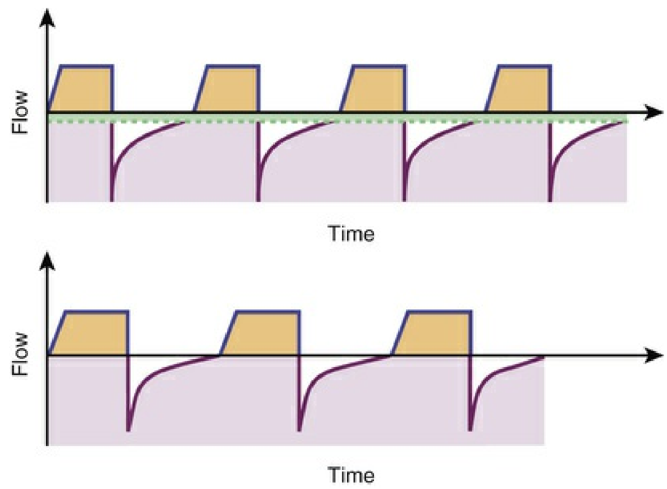

FIG. 53.6 Schematic representation of the airway flow tracing over time during volume control ventilation. *Upper panel:* Expiratory flow does not return to zero prior to the initiation of the following breath, resulting in auto-PEEP. *Lower panel:* Expiratory flow returns to baseline prior to the initiation of the following breath after optimization of ventilator settings (lower respiratory rate and longer expiratory time).

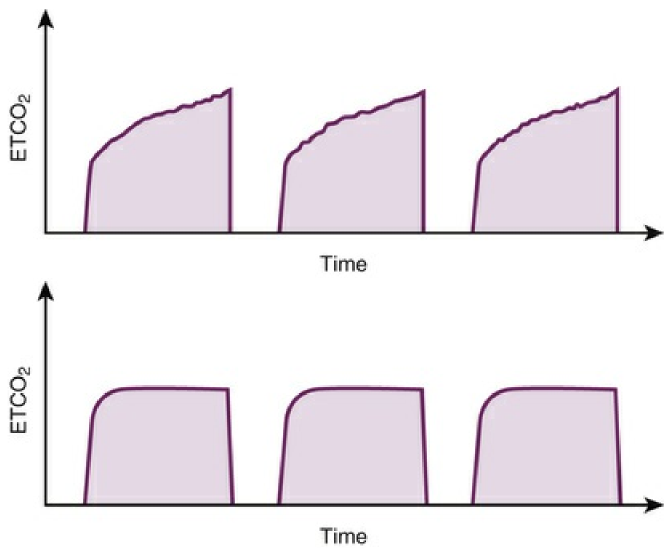

FIG. 53.7 Schematic representation of a capnogram in near-fatal asthma *(upper panel)* and under normal conditions *(lower panel)*. Severe airflow obstruction in persons with near-fatal asthma is manifested by sloping of the expiratory phase tracing and absence of a plateau, suggesting incomplete exhalation prior to the following inspiration. *$ETCO_2$,* end-tidal carbon dioxide.

Analgesia, Sedation, and Muscle Relaxation

Patients with near-fatal asthma undergoing mechanical ventilation require adequate analgesia and sedation to avoid tachypnea, breath stacking, and ventilator dyssynchrony, particularly in the setting of hypercapnia. Ketamine is the anesthetic agent of choice because of its bronchodilatory properties. Its use with continuous

infusions of midazolam or lorazepam can provide deep sedation while decreasing the chance of postanesthetic hallucinatory reactions. Despite its bronchodilatory effects, some practitioners do not favor the use of ketamine because of concerns about the negative impact of increased secretions on an already hypersecretory and narrowed airway. When opiates are used instead, fentanyl is the preferred agent because morphine can cause histamine release and, theoretically, aggravate an acute attack.

Muscle relaxation with neuromuscular blockers should be maintained following initiation of mechanical ventilation until satisfactory gas exchange and clinical stability are achieved. Patients who exhibit significant hypercapnia during mechanical ventilation require continuation of neuromuscular blockers to abolish spontaneous respiratory movements that could worsen dynamic hyperinflation. However, use of neuromuscular blockers should be discontinued as soon as feasible to reduce the likelihood of serious neurologic complications, such as prolonged muscle weakness or paralysis, from the interaction of these agents and corticosteroid drugs.[193,194] Reports of prolonged paralysis and myopathy after the concomitant use of corticosteroid drugs and aminosteroid-based neuromuscular blockers, such as vecuronium and pancuronium, led to the preferential use of benzylisoquinolinium compounds, such as cisatracurium, in patients with asthma. However, this combination may not be completely safe, because prolonged muscle weakness has also been observed after treatment with cisatracurium and corticosteroids.[195]

Inhalational Anesthetic Agents

Inhalational anesthetic agents have been used for their bronchodilatory effects in the treatment of mechanically ventilated patients with near-fatal asthma that is refractory to more conventional treatment modalities.[196] The exact mechanism responsible for bronchodilatation during inhalational anesthesia is unknown but may involve direct inhibition of vagal tone.[197] Various agents have been used successfully in both adult and pediatric patients with refractory near-fatal asthma, including halothane,[198] isoflurane,[199,200] enflurane,[201] and sevoflurane.[201,202] Sevoflurane compares favorably with halothane and appears to be less noxious to human airways than isoflurane or enflurane.[203]

Inhalational anesthetics can be delivered by means of an anesthesia machine that feeds into the low-pressure gas port of a conventional mechanical ventilator or via a dedicated anesthesia ventilator with its own vaporizer. It is important to ensure proper disposal of exhaled gases into a scavenger system to prevent release of the anesthetic agent into the environment. A monitor capable of continuously analyzing inspiratory and expiratory drug concentrations is helpful in ascertaining the actual amount delivered and signaling interruptions in therapy, such as those caused by an empty vaporizer reservoir or inadvertent failure to resume therapy after a refill. Usual doses of isoflurane range from 0.5% to 2% and should be titrated for effect. Clinical response usually can be observed within 30 minutes.

Therapy with an inhaled anesthetic agent for persons with refractory near-fatal asthma should be performed in a well-monitored ICU, under the direction of personnel experienced in the administration of these agents and knowledgeable in their adverse effects. Patients treated with halothane can experience significant hypotension as a result of myocardial depression and require rapid fluid expansion

and inotropic support.[204,205] Halothane is associated with cardiac arrhythmias, particularly during concurrent administration of epinephrine,[206] which explains why many physicians prefer a nonarrhythmogenic alternative such as isoflurane. Isoflurane does not have negative inotropic effects but may still cause hypotension because of vasodilatation.[177] Considering that halothane and isoflurane result in equivalent bronchodilation, isoflurane is preferred for use in children because of its less significant adverse effects. The use of subanesthetic doses of inhalational anesthetic agents in an attempt to avoid mechanical ventilation in spontaneously breathing patients with severe asthma during maximal medical treatment is an intriguing strategy that warrants further study.[207]

Antibiotics

In children, acute asthma exacerbations frequently are triggered by a viral infection. Thus antibiotic agents are not indicated as part of standard treatment. A subset of school-aged children may present to the hospital with shortness of breath, accessory muscle use, hypoxemia, and expiratory wheezing caused by *Mycoplasma pneumoniae* pneumonia that simulates an acute asthma exacerbation. These patients usually have bilateral interstitial disease on a chest radiograph and should be treated with appropriate antibiotics, such as a macrolide.

Patients with near-fatal asthma who require intubation and prolonged mechanical ventilation should be monitored for the development of nosocomial infections. The presence of fever and abundant thick white or purulent tracheal secretions warrants obtaining a protected tracheal specimen for Gram stain and culture to guide appropriate antibiotic coverage.

Bronchoscopy

Increased bronchial secretions and mucous plugging play a major role in the continued deterioration observed in some patients.[41-43] Mucous plugging and casts can cause atelectasis of large segments and worsen the heterogeneity of ventilation and dynamic hyperinflation. Thus a small percentage of mechanically ventilated patients with severe near-fatal asthma may require selective suction of mucous plugs, casts, or thick secretions by bronchoscopy.[208] The combination of bronchial lavage with mucolytic agents such as *N*-acetylcysteine[209] or recombinant human deoxyribonuclease[210] and aggressive selective suction through a bronchoscope may be beneficial in patients with clinically significant mucous plugging who fail to respond to maximal therapy and traditional tracheal suction.

Extracorporeal Life Support

The use of extracorporeal life support (ECLS) has been reported in the management of the very few patients with near-fatal asthma who continue to exhibit a profound degree of clinical instability despite maximal therapy.[211,212] Such cases are extremely unusual and constitute less than 1% of patients in the Extracorporeal Life Support Organization registry (256 of 32,975 [0.78%] pediatric and adult ECLS runs).[213] Interestingly, the survival rate for persons with near-fatal asthma necessitating ECLS

is approximately 83%,[213] which is remarkable considering that the majority of these patients were extraordinarily sick and had failed to respond to aggressive treatment.

Prognosis

The prognosis of patients with critical or near-fatal asthma who receive proper medical therapy is excellent. Better understanding of the pathophysiology of airway obstruction and dynamic hyperinflation, coupled with improved mechanical ventilation strategies and aggressive pharmacologic treatment, has reduced the ICU mortality rate to nearly zero in these patients.[7,214-216] Asthma fatalities still occur in patients with sudden onset of severe airway obstruction who do not come to medical attention prior to the development of respiratory failure or cardiorespiratory arrest.[217,218] The postdischarge treatment plan for patients admitted to the hospital with critical or near-fatal asthma should be carefully reviewed prior to discharge to ensure adequate outpatient therapy, education, and follow-up in an attempt to reduce the likelihood of a preventable recurrence. An asthma expert in addition to a pediatrician should follow such patients.

CHAPTER 54

Neonatal Respiratory Disease

Devaraj Sambalingam, Lewis P. Rubin

PEARLS

- Pulmonary or nonpulmonary disorders can lead to neonatal respiratory distress or failure.
- Increasingly, recognized variations in inherited risk and susceptibility to treatments in respiratory disorders relate to genetics, epigenetic change, intrauterine environment, race, ethnicity, and gender.
- The outcome of neonates with respiratory disorders greatly depends on early recognition of respiratory distress, the ability to distinguish respiratory disorders from the normal neonatal transition, and prompt intervention.
- The three most common reasons of respiratory distress are transient tachypnea of the newborn, respiratory distress syndrome, and persistent pulmonary hypertension of the newborn.
- Knowledge of cellular and molecular mechanisms of the pulmonary surfactant system has facilitated recognition of hereditary disorders previously described as idiopathic.
- In addition to respiratory distress syndrome, many other neonatal clinical respiratory disorders may be associated with *functional* surfactant deficiency.
- Noninvasive positive pressure ventilator techniques have dramatically reduced the need for endotracheal intubation.
- The term *congenital thoracic malformation* is recommended for all congenital lung and thoracic malformations; nomenclature and classification of these entities are evolving.
- In the neonate, significant congenital heart disease can present as (1) cyanosis with minimal or no respiratory distress or (2) cardiorespiratory failure.

Respiratory distress in the newborn is a frequent cause of admission to special care nurseries, second only to prematurity/low birth weight, and occurs in up to 7% of all newborn infants.[1] The rise in cesarean sections and the growing numbers of premature deliveries have increased the incidence of respiratory distress in the

newborn.

Effective gas exchange within the lung requires both adequate ventilation and perfusion. Determinants include central respiratory drive, muscle strength, chest wall recoil, right ventricular output, and pulmonary vascular resistance. Consequently, a wide range of pulmonary and nonpulmonary derangements can lead to respiratory insufficiency.

Lung Maturation and Physiologic Changes at Birth

Branching morphogenesis is mediated by complex signaling and transcriptional programs. Thyroid transcription factor–1(TTF-1), SOX2 (larger airways), and SOX9 (smaller airways and epithelial cells) are required for branching and cell differentiation.[2-6] The developing human lung evolves through embryonic (<7 weeks), pseudoglandular (7-17 weeks), canalicular (16-26 weeks), saccular (26-37 weeks), and alveolar (36 weeks into childhood) stages. Surfactant production by type 2 epithelial cells accelerates from 36 weeks onward.

A critical adaptive change for newborns is intolerance to lower PaO_2 compared to fetal life the few minutes before birth. This complex and incompletely understood mitochondrial switch occurs in both term and preterm babies. Lung expansion, clearance of lung fluid, and cardiopulmonary changes following cord clamping lead to increased systemic vascular resistance and decreasing pulmonary vascular resistance with resultant decreased shunting across the ductus arteriosus and it eventual closes. In the first approximately 6 hours following birth, adequate functional residual capacity (FRC) is achieved, intrapulmonary shunting decreases, and a regular rhythmic, modulated respiratory pattern is established. Any disruption in this cardiopulmonary transition may manifest as respiratory distress in the form of tachypnea (>60 breaths/min), cyanosis, expiratory grunting, chest retractions, and nasal flaring.

Acute or Early-Onset Respiratory Disorders

Transient Tachypnea of the Newborn or Retained Fetal Lung Liquid Syndrome

The chloride-rich fetal lung fluid is actively secreted at a rate of 4 to 5 ml/kg/h (measured in fetal lambs),[7] maintaining a pressure in the presumptive airways of +2 cm H_2O, which is critical for lung growth.[8] Secreted lung mixes with amniotic and is swallowed by the fetus. The high resistance in the upper airway in the fetus relaxes during fetal lung excursions (breathing movements); the combination of swallowing and diaphragmatic contractions maintains pressure for continued respiratory tract expansion and growth. The mechanisms of fetal lung liquid production and reabsorption involve active ion transport and hormonal regulation[9] (Fig. 54.1).

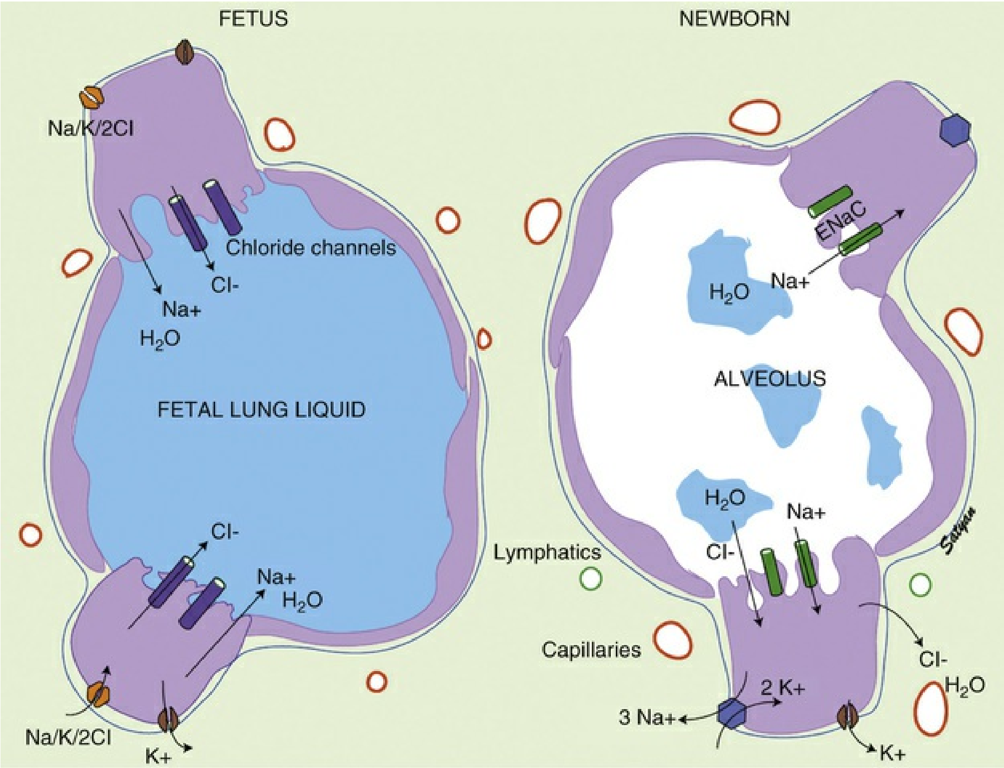

FIG. 54.1 Mechanism of fetal and neonatal lung fluid transport. (Modified from Guglani L, Lakshminrusimha S, Ryan RM. Transient tachypnea of the newborn. Pediatr Rev. 2008;29:e59-65. Copyright Satyan Lakshminrusimha.)

Chloride ions enter the developing terminal air sac epithelium from the basolateral membrane via a Na/K/2CL cotransporter (the transporter on which furosemide acts). Transepithelial (reabsorptive) movement of lung fluid at the time of birth involves passive movement of sodium through epithelial sodium channels (ENaC),[10] which are inactive during fetal life and are activated during parturition by adrenergic stimulation. Although β-adrenergic agents such as terbutaline and epinephrine enhance Na ion trafficking and liquid reabsorption, in animal studies β-adrenergic blockade does not inhibit the reabsorption of lung liquid during spontaneous labor and delivery. Additional hormones of parturition, such as vasopressin, may contribute to this process.

The pulmonary circulation also plays a key role in fetal lung fluid clearance; interstitial liquid drains directly into the circulation, and the dramatic increase in pulmonary blood flow occurring after birth enhances reabsorption of liquid from fetal airspaces. It is estimated that lung fluid approximates to 20 to 30 mL/kg near term.[11] In the hours to days leading up to delivery, net lung fluid accumulation diminishes and, during labor, reabsorption predominates. As a result, extravascular lung liquid volume (ie, liquid within the airspaces and interstitium) decreases. Any excess fluid remaining within the airspaces at the time of delivery is further resorbed as air entry into the lungs displaces liquid from the airways into the interstitium. Residual interstitial liquid is then taken up into the circulation over the next several hours, partly due to the dilatation of lymphatic channels resulting from paracrine interactions. Excessive residual extravascular liquid can impair gas exchange as interstitial liquid pressure compresses small airways leading to atelectasis and gas trapping. Excess liquid remaining within airspaces will impair alveolar gas

exchange.

The onset of breathing increases the surface area for liquid reabsorption and is associated with the opening of pores through which liquid can readily enter the interstitium. Drainage of interstitial liquid is generally complete by the end of initial neonatal transition (4 to 6 hours). Interstitial liquid appears to be directly absorbed into the microcirculation in a process governed by Starling forces; the contribution of lymphatic drainage appears to be negligible. Retention of liquid in airspaces and interstitium leads to impaired gas exchange and respiratory distress with variable clinical presentations.

Excess liquid within the airspaces also reduces compliance and increases intrapulmonary shunting, which results in tachypnea and mild to moderate hypoxemia. The chest radiograph may show opaque areas similar in appearance to neonatal pneumonia or surfactant-deficient respiratory distress syndrome (RDS). This picture is sometimes described as “prolonged neonatal transition” or “delayed extrauterine adaptation.” Excess interstitial liquid reduces compliance and compresses small airways, which leads to the clinical signs of tachypnea and air trapping. The chest radiograph may show streaky densities within the lung (wet lung), fluid collection within interlobar fissures, or even small pleural effusions; the lungs may also appear hyperinflated because of gas trapping. This clinical picture is often termed *retained fetal lung liquid* or *transient tachypnea of the newborn (TTN).*

Delayed fetal lung liquid clearance represents the most common type of respiratory disorder in the neonate and occurs in an estimated 3.6 to 5.7 per 1000 term infants and in up to 10 per 1000 preterm infants. Infants who are born precipitously or by cesarean delivery, those who are male, and those born to mothers with diabetes are at highest risk for this disorder.[12-14] The differential diagnosis includes neonatal pneumonia and meconium aspiration syndrome. Definitive diagnosis is often retrospective, once the respiratory signs resolve, most often within 1 to 5 days and requiring minimal interventions.

Infants stressed in utero or whose mothers have received β-mimetic agents are less likely to have retained lung liquid. Preterm infants who have a TTN-like presentation may be mistakenly assumed to have surfactant-deficient RDS. In both instances, supportive treatment is similar, although surfactant therapy is not indicated for infants with TTN. The clinical severity of TTN varies widely. Although most infants can be treated with supplemental oxygen alone, others may require intubation and mechanical ventilation for 12 to 24 hours. In these latter instances, TTN resembles an amniotic fluid aspiration syndrome. Supplemental oxygen is usually necessary for not more than 24 to 48 hours, but tachypnea may persist for several days. In addition, reactive airway disease is more likely to develop later in life in newborns who present with transient respiratory distress.

Surfactant-Deficient Respiratory Distress Syndrome

A seminal study by Avery and Mead in 1959[15] demonstrated that hyaline membrane disease, now termed *respiratory distress syndrome (RDS)* of the newborn is caused by a lack of pulmonary surfactant in preterm newborns. The phospholipids, proteins, genes, and cellular processes of surfactant biosynthesis and recycling were subsequently elucidated.

RDS is a primarily a disease of prematurity. The incidence of RDS decreases with

increasing gestational age, with occurrence in approximately 60% of babies born at less than 28 weeks of gestation 30% born between 28 to 34 weeks, and 5% born after 34 weeks.[16-18] Risk factors for RDS include prematurity, male sex, maternal gestational diabetes, perinatal asphyxia, hypothermia, and multiple gestations.

Surfactant-deficient alveoli are more prone to collapse, leading to diffuse atelectasis and the classic ground glass appearance of chest radiographs. There is reduced ventilatory compliance, atelectasis, and intrapulmonary shunting. Infants with surfactant deficiency have stiff, noncompliant lungs and require significant distending pressure for lung expansion and adequate ventilation. Affected neonates exhibit tachypnea, respiratory muscle (diaphragmatic, subcostal, and intercostal) retractions, and expiratory grunting. Complications include pulmonary air leak, pulmonary hemorrhage, intracranial hemorrhage, and chronic lung disease. Infants who require prolonged intubation and mechanical ventilation also are at risk for subglottic injury including subglottic stenosis and tracheomalacia. Before the availability of exogenous surfactant therapy, the mortality rate from RDS exceeded 20%; currently, infants treated in neonatal intensive care units (NICUs) rarely succumb to RDS unless they are extremely preterm or suffer severe complications.

Pulmonary surfactant disperses at the air-liquid interface of alveoli, reduces surface tension at this interface, and prevents alveolar collapse at end expiration. Pulmonary surfactant consists of lipids 90% and proteins 10%. Phospholipids (including phosphatidylcholine [PC] and phosphatidylglycerol [PG]) are enriched surfactants produced by alveolar type 2 pneumocytes. The lipids are synthesized in the endoplasmic reticulum and transferred into lamellar bodies (LBs) via an ATP-binding cassette transporter A3 (ABCA3) pathway.[19-21] The hydrophobic surfactant apoproteins (SP-B and SP-C) are assembled into LBs and secreted into the alveolar space with lipids via G-protein coupled receptor (GPR 116)[22,23] at the epithelial surface. Under the influence of extracellular calcium ions, the LBs then unwind and interact with hydrophilic surfactant proteins (SP-D and SP-A) to form a tubular myelin mesh, which spreads into the surfactant film surface monolayer. Surfactant is also recycled and catabolized or reutilized. Maintenance of the surface film is a dynamic process. The unique surface tension–lowering property of surfactant is principally due to dipalmitoyl phosphatidylcholine (DPPC), a disaturated phospholipid in which acyl groups are tightly interlaced as the film is compressed during exhalation. Phospholipids containing unsaturated acyl chains and cholesterol maintain fluidity at body temperature. During inhalation, SP-B and SP-C help incorporate and spread lipids in the surface lattice.

Assessment of fetal lung maturity using phospholipid analysis of amniotic fluid and maternal glucocorticoid therapy, both introduced in the mid-1970s, has reduced the incidence of RDS in preterm infants. Prophylaxis and treatment with exogenous intratracheal surfactant in neonates with signs of respiratory insufficiency during the first days of life have significantly reduced the clinical severity of RDS and improved survival.

Genetic Disorders of Surfactant Homeostasis

Mutations in the genes encoding SP-B (SFTPB), SP-C (SFTPC), and ABCA3 (ABCA3) and CSF2RA and CSF2RB (GM-CSF receptor) can cause refractory respiratory failure and chronic interstitial lung disease in full-term infants, despite mechanical ventilation and surfactant replacement.[24]

SP-B mutations (often autosomal recessive) can result in a complete loss of SP-B. Affected patients almost always present with respiratory failure in the neonatal period and usually die (without lung transplantation) in the first few months of life. SP-C mutations are inherited as an autosomal dominant disorder, can present in infancy or later childhood, and are variable in severity. ABCA3 and CSFR mutations are inherited as autosomal recessive disorders and can present as a neonatal form or much later in life as chronic childhood interstitial lung disease (chILD syndrome).[19] Histopathologic changes resulting from these gene mutations include pulmonary alveolar proteinosis in the more severe neonatal form and chronic interstitial pneumonitis in the later-onset, less severe forms.

Congenital alveolar proteinosis is a rare disease entity with histopathologic similarities to alveolar proteinosis occurring in older children and adults. However, the clinical course of congenital alveolar proteinosis is severe, with rapid progression to death within several hours to days.

Therapeutic bronchoalveolar lavage has been helpful in adults and some children with alveolar proteinosis, but it has not been systematically studied in infants with congenital disease. Extracorporeal support does not alter the long-term prognosis of infants who have this condition. To date, the only survivors are those who have undergone lung transplantation. Molecular genetic diagnosis can identify affected infants and help predict fatal outcome, permitting more individualized counseling for parents whose infants have this fatal disorder.

Pulmonary Air Leak Syndromes

Pulmonary air leak syndrome encompasses a spectrum of entities including pneumothorax, pneumomediastinum, pneumopericardium, and pulmonary interstitial emphysema (PIE). Subcutaneous emphysema and pneumoperitoneum are rarer forms.

As a group, pulmonary air leaks are more common during the neonatal period than at any other time of life. The two most common types of air leak, pneumothorax and pneumomediastinum, occur spontaneously in 1% to 2% of term neonates[25] and are apparently symptomatic only in an estimated 10% of these newborns. Preterm infants with surfactant-deficiency RDS historically had reported rates of air leaks in excess of 30%; these rates fell rapidly with the advent of surfactant therapy in the 1980s but still remain at about 5%.[26] Infants who have meconium aspiration or hypoplastic lungs have much higher air leak rates.

Air leak initiates as rupture of an overdistended alveolus. Overdistention may be due to generalized air trapping or uneven distribution of air. Alveoli most susceptible to this injury are those that border on arterioles and other structural elements of the lung, locations where more uniform protection by surrounding alveoli is lacking. After rupture of the alveolus or terminal airspace, air escapes into the lung interstitium and tracks along the perivascular connective tissue sheaths toward the hilum. If air leaks into the intrapleural space, pneumothorax results. If the leak is at the hilar pleural reflection, pneumomediastinum occurs; air leak at the pericardial reflection results in pneumopericardium. Rarely, air can dissect into the soft tissue planes of the neck, causing subcutaneous emphysema, or across the diaphragmatic apertures and into the peritoneal abdominal space, leading to a pneumoperitoneum.

In the past, pulmonary air leaks most commonly occurred as a result of excessive ventilatory pressures due to either overly aggressive mechanical ventilation (barotrauma) or air trapping caused by partial airway obstruction by meconium or other debris *(ball valving)*. More recently, air leaks are more commonly seen during the recovery phase of acute respiratory disease, when lung compliance dramatically improves and pressure-limited ventilation leads to excessive tidal volumes (volutrauma). This phenomenon explains the clinical observations that air leaks tend to occur during the recovery phase of RDS and why the incidence of air leaks actually increased during early trials of surfactant therapy. Both observations underscore the need to closely monitor ventilatory volumes and wean pressure aggressively as compliance improves. Moreover, evidence indicates volume-limited ventilation may be a safer mode for neonatal mechanical ventilation, even during the recovery phase of acute neonatal respiratory disease.

Pneumomediastinum is one of the most common air leaks and, considering the pathways by which air will track, is often the harbinger of further air leaks. Infants with isolated pneumomediastinum generally display few or no signs other than chest x-ray low-density widening of the mediastinum. Distention of the mediastinum has the potential to compress the great vessels and compromise circulation. This situation rarely occurs in clinical practice because air will usually track into the soft tissues of the neck and scalp or rupture into the pleural spaces before pressure needed for circulatory compromise is attained. On an anteroposterior view of the chest x-ray, air may form a lucency around the heart, whereas on a lateral view, air lifts the lobes of the thymus away from the cardiac silhouette *(spinnaker sail sign)*.

Pneumothorax is a clinically common and more worrisome form of pulmonary air leak. The initial signs of pneumothorax result from lung compression and diminished lung compliance. If compromise is minimal, the infant will maintain minute ventilation simply by increasing ventilatory rate (tachypnea); an additional sign may be increased use of accessory muscles (retractions) in an effort to improve tidal volume. If positive pressure within the pleural space builds to the point of vascular compromise (ie, tension pneumothorax), cardiac return will decrease, and the heart rate will rise to compensate for diminished stroke volume. Eventually, blood pressure may fall and, if oxygen delivery cannot be maintained, bradycardia and cardiopulmonary arrest may ensue.

Pneumopericardium is a rare but often life-threatening form of pulmonary air leak. The clinical signs closely resemble those of tension pneumothorax, with the addition that diminished heart sounds are invariably present. Mortality may be as high as 80%. Diagnosis is suspected if an infant experiences acute circulatory collapse; it is confirmed by lucency around the heart on x-ray or by return of air on pericardiocentesis using an angiocatheter and syringe.

Pneumoperitoneum occurs when air dissects from the chest through a foramen of the diaphragm. This condition is generally benign and causes little clinical difficulty. It can, however, be confused with perforation of a viscus. Pneumoperitoneum is often distinguishable from bowel perforation by a clinical history of a prior pneumomediastinum or pneumothorax, especially when there is an absence of gastrointestinal signs. Although pneumoperitoneum usually requires no treatment, it may occasionally compromise ventilation. In that case, aspiration of air from the pneumoperitoneum is both therapeutic and diagnostic; oxygen tension in ventilatory

gas is markedly higher than that in bowel gas.

PIE is a more severe manifestation of the same pathophysiologic process that leads to other air leak syndromes. In this instance, air accumulates in the interstitial space rather than tracking toward the hilum. The chest x-ray may show a variable number of cystic or linear lucencies in the lung fields. Some lucencies may be elongated or sausage shaped; others appear as enlarged subpleural cysts ranging in size from a few millimeters to several centimeters in diameter.[27,28] This air accumulation produces compression of the airways and vasculature, making ventilation more difficult. This situation creates a need for higher airway pressures in order to maintain open airways, which, in turn, can increase the air leak and therefore the PIE. Avoiding this escalation of therapy is a primary principle in the treatment of PIE.

The approach to management of air leaks in infants is similar to that in older children. Pneumothorax, pneumopericardium, and occasionally pneumoperitoneum are acute, life-threatening emergencies because they can seriously impair cardiac output by decreasing venous return. There should be a high degree of suspicion for air leaks in a patient who has a sudden, unexpected cardiovascular deterioration. Transillumination of the relatively translucent neonatal chest wall using an intensely focused light source is a quick and useful tool for diagnosing a large pneumothorax. Immediate aspiration of the air, preferentially with a large bore angiocatheter, should be done even before radiographic confirmation if the infant is severely compromised. An unstable or recurrent pneumothorax may require a thoracotomy tube. However, tube thoracostomy can be associated with significant complications, including parenchymal lung injury, phrenic nerve paralysis, chylothorax, and hemorrhagic pericardial effusion. Penetration of the chest tube into the pulmonary parenchyma is a complication that often is not appreciated by chest radiographs. One study of autopsies of infants with pneumothorax reported a lung perforation rate of 25%.[29,30]

Cardiac tamponade resulting from a pneumopericardium may be suggested by distant heart tones and hypotensive shock with a normal-appearing electrocardiogram tracing *(electromechanical dissociation)*. Pneumomediastinum often is asymptomatic and rarely benefits from drainage, even in the presence of clinical signs. PIE occurs predominantly in preterm infants and often leads to a vicious cycle of increasing ventilator delivery pressures to open alveoli compressed by extrinsic air, which, in turn, leads to more extravasation of air and further collapse. Previously used treatment maneuvers for PIE, including positioning, selective main stem intubation, and steroids, have been unsatisfactory.

Both high-frequency oscillatory ventilation (HFOV) and high-frequency jet ventilation (HFJV) can provide adequate gas exchange using extremely low tidal volumes and a supraphysiologic rate in neonates with acute pulmonary dysfunction, and they may reduce the potential risk of air leak syndrome in neonates.[31] However, there is no conclusive evidence that HFOV or HFJV reduces the incidence of air leaks in neonates.[32,33]

Pulmonary Hemorrhage

Pulmonary hemorrhage (PH) in the newborn is a life-threatening condition that has an incidence of 1 to 12 per 1000 live births and 50 per 1000 high-risk infants.[34] Risk

factors for PH include prematurity, intrauterine growth restriction, patent ductus arteriosus (PDA) with systemic steal, asphyxia, congenital heart disease, coagulopathy, RDS, surfactant therapy, hypothermia, multiple births, oxygen toxicity, male gender, urea cycle defects, meconium aspiration, and the need for positive pressure ventilation. Antenatal corticosteroids seem to be protective.

In most cases, what is called pulmonary hemorrhage is actually the most severe manifestation of pulmonary edema rather than anatomic vascular disruption. This conclusion is validated by determining measures of the hematocrit of hemorrhagic fluid suctioned from the airway. The hemorrhagic fluid hematocrit generally will be 15% to 20% lower than venous hematocrit in the same patient at the time. Finding whole blood in the airway is rare and usually results from trauma from mechanical injury.

The major forces involved in this process seem to be circumferential tension in the capillary wall secondary to capillary transmural pressure, surface tension of the alveoli that supports the bulging capillaries, and longitudinal tension in the alveoli as a result of lung inflation.[34-37] Factors that alter capillary transmural pressure are increased perfusion pressure (eg, left ventricular failure), increased pulmonary blood flow (eg, from a left-to-right shunt across a PDA), increased microvascular permeability (eg, associated with sepsis or oxygen toxicity), and decreased oncotic pressure (eg, protein malnutrition or water overload). Most infants with PH will have more than one risk factor. In the neonate, the factors most commonly associated with hemorrhagic pulmonary edema are those that increase pulmonary blood flow, such as a left-to-right shunt or treatment with surfactant. PH also has been associated with neurologic disorders, including seizures, stroke, subarachnoid hemorrhage, and massive intraventricular hemorrhage. Sudden improvement in lung compliance after surfactant therapy, with resultant decrease in pulmonary vascular resistance producing increased left-to-right shunting, may lead to PH. Hypothermia causes platelet aggregation that can result in thrombocytopenia, a process that continues or accelerates upon warming.

The diagnosis is made when the appearance of bloody secretions within an endotracheal tube coincides with acute respiratory deterioration that requires increased oxygen and ventilator support. The chest radiograph is nonspecific and may show fluffy opacities, focal ground-glass opacities, or appear as a complete whiteout of the lung fields.

The goal of management is to stop hemorrhage while maintaining adequate gas exchange. Increasing positive end-expiratory pressure (PEEP) reduces alveolar flooding and can improve oxygenation and left ventricular function. Although the airway must be kept clear, frequent suctioning not only may be traumatic but also can aggravate the condition by reducing PEEP. High mean airway pressures, which can be safely achieved with high-frequency ventilation (HFV), can be effective in massive pulmonary hemorrhage yielding rapid improvement in oxygenation.

Administration of endotracheal or nebulized epinephrine or iced saline solution via the endotracheal tube has been advocated in the past but has questionable efficacy, and epinephrine may worsen the condition by elevating pulmonary vascular pressure. Aggressive volume resuscitation also should be avoided for the similar reasons. Antibiotics should be considered if sepsis is suspected, but the efficacy of prophylactic antibiotics to prevent bacterial contamination of the airways is unproved. If an underlying cause such as a PDA or coagulopathy is suspected, it

should be treated.

Additional therapies that may be beneficial in specific instances include surfactant, recombinant activated factor VII (rFVlla), and hemocoagulase.[38-40] The rationale for surfactant therapy is that red blood cell products, including hemoglobin, proteins, and lipids, can inactivate the infant's pulmonary surfactant.[41] Recombinant FVlla is a vitamin K–dependent glycoprotein that activates the extrinsic pathway and binds to tissue factor promoting sealing of vascular injury sites and restoring hemostasis. Its effect may be augmented by concomitant transfusion of platelets. Hemocoagulase is a purified enzyme mixture that has a thromboplastin-like effect by converting prothrombin to thrombin and fibrinogen to fibrin.

Prevention also may be possible in some cases; in preterm infants at high risk for the development of hemodynamically significant PDA, indomethacin prophylaxis appears to reduce the incidence of severe hemorrhagic pulmonary edema.

Even with aggressive management, mortality from hemorrhagic pulmonary edema may exceed 25%. The Trial of Indomethacin Prophylaxis in Preterm infants (TIPP) study (post-hoc analysis) showed risks of death or survival with neurosensory impairment were doubled after serious PH. Approximately 60% of preterm infants who survive PH developed bronchopulmonary dysplasia. An increased incidence of cerebral palsy and cognitive delay (odds ratio 2.86 and 2.4, respectively)[42] has been reported. PH is also associated with an increased risk of seizures and periventricular leukomalacia in survivors at 18 months of age.[43]

Pneumonia

Neonatal pneumonia is a common cause of significant morbidity and mortality. In developed countries, term infants have an incidence of <1%, whereas the incidence in preterm and sick infants may approach 10%.[44] The World Health Organization (WHO) estimated approximately 800,000 infants die annually from neonatal respiratory infections, mostly pneumonia.[45] Neonatal pneumonia can be congenital (acquired before labor and rupture of amniotic membrane via hematogenous or ascending infection or by aspiration), intrapartum (acquired during labor via ascending or hematogenous infection), or postnatal (acquired after birth).

The lungs represent the most commonly affected organ in neonates with sepsis. Bacterial or viral infection in the neonate may begin in utero, by transplacental passage or, more commonly, by ascending infection from the maternal genital tract or by hematogenous spread. Prolonged rupture of membranes (>18 hours) increases the risk of an ascending infection, although some organisms may invade through intact membranes. Cervical bacterial colonization with group B streptococci (GBS) or primary herpes viral cervical infection during pregnancy increases the risk of transmitting those diseases. Nevertheless, routine cervical cultures taken during pregnancy often do not reliably predict bacterial flora present at the time of delivery. Also, infants born vaginally are invariably colonized with organisms from the vaginal canal and typically swallow organisms during vaginal passage. Cesarean delivery is not necessarily protective because fetuses may swallow contaminated amniotic fluid or aspirate organisms in utero. Infection occurring during the perinatal period may not present clinically for several days. Consequently, congenitally acquired infections may be indistinguishable from infections postnatally acquired (ie, nosocomial).

As a result, organisms that cause perinatal pneumonias are typically those found in the genital tract of the mother and include streptococci (groups A, B, and D), gram-negative rods (eg, *Escherichia coli* and *Klebsiella* species), *Listeria monocytogenes*, ureaplasma, genital hemophilus, and herpesvirus. Although the incidence of GBS pneumonia has decreased dramatically due to maternal screening and intrapartum treatment, GBS remains a common bacterial cause of neonatal pneumonia.

GBS expresses a pore-forming cytolysin (beta-hemolysin), which is inhibited by surfactant phospholipid. Consequently, in preterm babies, morbidity is higher. Less commonly, maternal viral infections (eg, adenovirus, enteroviruses, or varicella) can be vertically transmitted to the fetus. Although perinatal tuberculosis is rare compared with other causes of neonatal pneumonia, there is an increasing prevalence of this disease in women of child-bearing age. Perinatal infection with other organisms, most typically chlamydia, may not present for several weeks. *Citrobacter diversus* is associated with abscess formation in the brain and lungs.[46] *Bacillus cereus* is associated with a necrotizing form of pneumonia and has frequently been found in contaminated ventilator circuits.[47,48]

Pneumonia may develop as a nosocomial infection in neonates, particularly in those who require mechanical ventilation for other critical illnesses. Although reported rates vary widely, in part because of the lack of a diagnostic standard in this population, some authors have suggested that the incidence of ventilator-associated pneumonia (VAP) may be as high as 30% in selected NICU populations. In addition to the presence of an endotracheal tube, risk factors for VAP include low birth weight, prolonged mechanical ventilation, sedation with opiates, frequent endotracheal tube suctioning, and crowding that is typical in some units. If a VAP is suspected, typical nosocomial pathogens such as staphylococcus, Klebsiella and Pseudomonas species, and the pathogens previously listed for congenital pneumonias should be considered as possible causes. *U. urealyticum* and *U. parvum* have frequently been recovered from endotracheal aspirates shortly after birth in very low-birth-weight infants and have been variably associated with various adverse pulmonary outcomes, including bronchopulmonary dysplasia.

Diagnosis of congenital pneumonia may be challenging because clinical and radiographic signs may be nonspecific. Although congenital infections are generally introduced through the respiratory tract, signs are rarely limited to those of pneumonia; the neonate is particularly prone to rapid dissemination of either bacterial or viral infections and typically has signs of sepsis or meningitis in addition to respiratory distress. The chest radiograph initially may appear normal, except for slight streakiness or hyperinflation, or the lung fields may be sufficiently opaque to be confused with surfactant-deficient RDS. Meconium aspiration with resultant severe chemical pneumonitis may be indistinguishable radiographically from bacterial pneumonia. Heart failure or obstructed anomalous pulmonary venous drainage also can present with a clinical and radiographic picture similar to pneumonia/sepsis.

Congenitally acquired pneumonia/sepsis can be a rapidly fatal disease, especially in the case of group B streptococcal or herpetic viral infections, for which mortality rates as high as 50% have been reported. A high degree of suspicion is therefore warranted. Antibiotics are routinely used in neonates with suspected pneumonia or sepsis and antiviral therapy should be considered if the infant has systemic signs such as shock or disseminated intravascular coagulation or is not responding to

initial therapy.

Revised guidelines for antenatal screening and antepartum prophylaxis published by the Centers for Disease Control and Prevention in 2010[49] aim to improve the screening rate of pregnant women. The further guidelines from the Committee of the Fetus and Newborn of the American Academy of Pediatrics (COFN) in 2013 have helped to focus the management of infants born after maternal chorioamnionitis.[49] Also, because current microbiologic screening may not identify all GBS carriers, GBS continues to be an important cause of early-onset neonatal sepsis. Vaccination may be the most effective means for preventing neonatal GBS disease, and this issue is currently under review.

Meconium Aspiration Syndrome

Passage of meconium in utero is a sign of fetal distress (acute or chronic) and occurs because of relaxation of the fetal anal sphincter. Moderate distress occurring during labor results in passage of meconium in the final stages of delivery (terminal meconium), whereas more severe or chronic distress results in earlier passage, with resultant staining of the amniotic fluid and fetus. Meconium staining is a significant marker of fetal distress and occurs in 10% to 20% of all deliveries, but meconium aspiration syndrome (MAS) occurs in only 4% to 5% of these; MAS is most common in postmature infants.[50-52] Intrauterine meconium passage is a maturational phenomenon meconium; it is rarely observed in fetuses younger than 34 weeks' gestation. Maternal risk factors for MAS include preeclampsia, diabetes, chorioamnionitis, and illicit substance use.

Meconium is a lipid- and protein-rich substance containing desquamated cells from the gastrointestinal (GI) tract, skin, lanugo hair, bile salts, pancreatic enzymes, and mucopolysaccharides and is highly irritating to mucous membranes of the distal airways, resulting in a chemical pneumonitis. Dissolved meconium may travel down the respiratory tree and inactivate pulmonary surfactant. Meconium induces a potent inflammatory response, and MAS is associated with alterations in the pulmonary vasculature, including remodeling and thickening of the vessel muscle walls. This process results in pulmonary vascular hyperreactivity, vasoconstriction, and high resistance and pressure. Activation of the complement cascade leads to inflammation and constriction of pulmonary veins. As the proinflammatory cytokine profile improves, so does pulmonary function. More particulate meconium will remain trapped in small airways, and this can lead to a ball-valve type of gas trapping. In most cases, the meconium is gradually removed from the respiratory tract through phagocytosis, and normal pulmonary function returns in 5 to 7 days. In more severe cases, meconium aspiration syndrome may lead to respiratory failure, and even death, despite aggressive intervention.

Infants with meconium aspiration are typically postmature and exhibit elongated nails, peeling skin, and staining of the umbilical cord, skin, and nails. Respiratory distress develops shortly after birth. The infant's respirations initially may be depressed if meconium passage occurred in response to a recent intrauterine asphyxial episode. Gas trapping may lead to a barrel-shaped appearance of the chest, and respiratory distress may be severe. Chest radiographs often show characteristic patchy densities, hyperinflation, and areas of collapse. Air leaks are especially common. Aspiration of blood during delivery results in a similar clinical

and radiographic picture. However, blood aspiration usually has a much milder course.

Routine airway suctioning on the perineum or routine endotracheal suctioning for all meconium-stained newborns is no longer recommended. The American Academy of Pediatrics and American Heart Association Neonatal Resuscitation Program currently recommends that visualization of the airway and suctioning should be limited to infants who are not vigorous at delivery. Because MAS results in a ventilation-perfusion mismatch, severe hypoxemia may occur and further elevate pulmonary vascular resistance.

Another antenatal intervention aimed at reducing disease from meconium aspiration is amnioinfusion, the process of instilling isotonic fluid into the amniotic space before delivery. The theoretic benefits of this approach include dilution of thick meconium and reducing cord compression by providing support to the umbilical cord. However, a large randomized clinical trial has questioned the efficacy of this practice.[53] Distressed fetuses may aspirate in utero, long before delivery. Severe complications such as persistent pulmonary hypertension of the newborn (PPHN) are more likely to be the result of the antecedent stress and are not due to meconium aspiration per se.

Supplemental oxygen to maintain arterial oxygen saturation, endotracheal suctioning to clear remaining meconium, and ventilatory strategies aimed to minimize gas trapping have been mainstays of management. HFV may help to prevent the development of air leaks. Antibiotics are commonly used because distinguishing the clinical and radiographic picture from sepsis is difficult and because damage to the airways may predispose to subsequent bacterial infection. A systematic review of four clinical trials in term and near-term infants concluded that surfactant administration significantly reduced the need for extracorporeal membrane oxygenation (ECMO), although overall mortality was not affected.[54,55] Nevertheless, surfactant replacement therapy is sometimes combined with other therapies including high-frequency ventilation and inhaled nitric oxide.

Despite the intense inflammatory nature of meconium aspiration, the efficacy of steroid administration remains uncertain. Although several small randomized trials have suggested clinical improvement, the mortality rate for MAS remains high.

Because intrauterine meconium passage and MAS are frequently associated with a hypoxic event, long-term neurologic outcome remains guarded. The overall mortality rate for MAS in the United States remains at 1% to 2%.[51] Moreover, mortality from MAS resulting from severe parenchymal pulmonary disease and pulmonary hypertension is as high as 20%, and air leak syndromes occur in 20% of affected infants. Recent data suggest meconium aspiration during the perinatal period may be associated with an increased risk of reactive airway disease in early childhood. Induction of labor at 41 weeks' gestation reduces the risk of MAS and perinatal death without increasing the risk of cesarean section.

Congenital Malformations of the Lung

In utero the organ of gas exchange is the placenta and fetal viability does not depend on a functioning lung. Not surprisingly, substantial abnormalities of the lung can exist antenatally with little or no clinical indication until delivery of the neonate, when the lung must assume the function of gas exchange.

Pulmonary Hypoplasia

Both static and dynamic expansions of the fetal lung are important determinants of normal fetal lung development. Static lung expansion occurs as a result of fetal lung liquid production. Epithelial cells within the lung actively secrete fluid into the lung lumen, distending the future airspaces.

Inadequate production or excessive drainage of fetal lung liquid leads to pulmonary hypoplasia. Dynamic lung expansion occurs during fetal breathing movements, which are rhythmic and occur with increasing frequency during the latter part of gestation. Absent or abnormal fetal breathing also results in pulmonary hypoplasia. Hypoplastic lungs are small in volume and DNA content relative to body size. They have reduced numbers of alveoli (mean alveolar count, MAC), bronchioles, and arterioles per unit mass. Although its pathophysiologic origins are not well understood, pulmonary hypoplasia can result from impairment of normal fetal lung expansion. It generally occurs in conjunction with one of the following conditions: (1) a space-occupying lesion within a hemithorax, such as a diaphragmatic hernia, or a massive pleural effusions associated with fetal hydrops can cause pulmonary hypoplasia; (2) an inadequate thoracic cage, as occurs in some types of osteochondrogenesis like asphyxiating thoracic dystrophy or achondrogenesis may cause hypoplasia; (3) a deficiency of amniotic fluid (oligohydramnios), due to leakage (preterm rupture of fetal membranes) or underproduction (renal dysplasia), may have similar consequences; (4) inadequate vascular supply to the developing lung, as may be seen with pulmonary artery atresia, hypoplastic right heart syndrome, or tetralogy of Fallot, may cause lung hypoplasia; (5) it may be due to an absence of fetal breathing movements; or (6) pulmonary hypoplasia may occur with chromosomal anomalies such as trisomy 13 or 18. If the insult occurs before the pseudoglandular stage of lung development (7 to 17 weeks), the degree of hypoplasia is severe. Pulmonary hypoplasia may occur in the absence of any of these conditions, but such cases of primary isolated pulmonary hypoplasia are rare.

Infants with pulmonary hypoplasia generally show signs of respiratory failure in the immediate newborn period. Reduced lung volume impairs ventilation and leads to hypercarbia. Decreased surface area for gas exchange (due to a reduced number of alveoli) leads to hypoxemia. A decreased cross-sectional area of the vasculature makes these infants particularly susceptible to pulmonary hypertension, which further exacerbates the hypoxemia. The chest radiograph in infants with pulmonary hypoplasia shows low lung volumes but may be otherwise unremarkable. The severity of the respiratory distress depends on the degree of hypoplasia and the presence of associated conditions such as fetal hydrops or cyanotic heart disease. The most common association is renal dysplasia or agenesis; in these cases, infants have a history of moderate to severe oligohydramnios and have severe respiratory distress and compression deformities of the face and extremities (Potter sequence). An antenatal sonographic assessment of lung-to-head ratio can be a useful predictor of pulmonary hypoplasia.

Treatment of infants with pulmonary hypoplasia is supportive, and outcome depends on the severity of the hypoplasia and the presence of associated lethal anomalies such as renal agenesis or achondrogenesis. The lungs of infants with severe pulmonary hypoplasia may be extremely difficult to ventilate, and

pneumothoraces are common because of the need for high distending pressures. HFV may be an effective means of ventilating these infants' lungs using a combination of high ventilatory rates with extremely low tidal volumes. Due to high impedence and delay in pulmonary vasculature development, the pulsatility indices are high, and peak systolic velocity is significantly lower than normal. Peak systolic velocity can be a marker of severity.

Survival depends on etiology or associated conditions. Survival rates due to congenital diaphragmatic hernia have improved and range from 60% to 70%. In certain forms of cystic adenomatoid malformation (CAM), the survival rates range between 25% and 30%.

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (CDH) occurs in approximately 1 in 2500 to 3000 live births and is the most common cause of pulmonary hypoplasia in the neonate.[56,57] At least 750 babies die of CDH in the United States annually, excluding a 15% prenatal termination rate. CDH can be associated with other anomalies as part of chromosomal defects, single gene defects (Denys-Drash syndrome, spondylocostal dysostosis, or neonatal Marfan syndrome), or multiple gene disorders. Most cases of CDH are nonsyndromic.

Failure of the pleuroperitoneal canal to close at 6 to 8 weeks' gestation results in a diaphragmatic defect that allows gastrointestinal structures to enter the thoracic cavity as the intestines return from outside the fetus into the abdominal cavity. The resulting mass effect in the chest impairs ipsilateral lung growth, characterized by a quantitative reduction in airways and their associated preacinar arteries. The defect occurs on the left side in 80% to 85% of cases, because closure of the right pleuroperitoneal membrane normally precedes the left during development. Because herniation often occurs before the 10th week of gestation when normal gut rotation occurs, malrotation is common. Nongastrointestinal anomalies are found in approximately 25% of cases; the most common involve the cardiovascular system. A wide variety of those have been reported. Other associated anomalies include esophageal atresia, trisomies (13, 18, and 21), Turner syndrome, neural tube defects, and renal anomalies. It has been assumed the pulmonary hypoplasia seen with CDH is secondary to mechanical forces, but studies in newborn babies and in animals have suggested that CDH may also be associated with nutritional deficiencies. In the rat model of nitrofen-induced CDH, prenatal retinoic acid improves alveologenesis[58-60]; experimental data regarding vitamin E supplementation have yielded conflicting results.

The clinical presentation of CDH depends on the degree of pulmonary hypoplasia present. In addition, the abdomen is often scaphoid because of a paucity of abdominal contents. As the infant cries and swallows air, the degree of lung compression may worsen, and an infant who appears healthy at delivery may undergo respiratory decompensation within minutes. The chest radiograph will show a cystic lesion in the lower lung field, often extending upward along the lateral chest wall. Initially, when the intestines remain fluid filled, the radiograph may be similar to that seen with pulmonary sequestrations or fluid-filled cysts. As the infant swallows more air, the radiographic findings may be confused with congenital emphysema or even pneumothorax. Small or right-sided defects may not present for

weeks or even months. Indeed, cases have occasionally been incidentally diagnosed during childhood when chest radiographs are obtained for other reasons. With the widespread use of antenatal sonography, most cases of CDH are diagnosed before birth, facilitating planned neonatal stabilization. In cases where sonographic findings are equivocal, prenatal magnetic resonance imaging may be particularly useful.

Initial management focuses on stabilization, including immediate endotracheal intubation and gastrointestinal decompression. Ventilation by bag and mask is avoided to prevent introducing more gas into the gastrointestinal tract. As with pulmonary hypoplasia, the clinical course may be complicated. CDH with persistent pulmonary hypertension may have a mortality of 80%. The introduction of neonatal ECMO has decreased early mortality, which nevertheless remains significant.[61,62] The contralateral non-hypoplastic lung in experimental CDH is functionally immature, implying potential benefit for surfactant therapy, but this maneuver has not been effective in a review of a large, national CDH registry.[63-65] In postmortem samples, concentration of SP-A has been dramatically reduced, more so in the affected lung than on the contralateral side.

Attempts at intrauterine intervention, either to close the defect or to encourage lung growth through temporary obstruction of fetal lung liquid egress at the trachea, have been disappointing. Fetal surgery for CDH has been associated with an unacceptably high incidence of complications, including recurrence of the defect, preterm delivery, and miscarriage.[66-68] Fetoscopic tracheal occlusion by clips or removable balloons[69] has also been attempted.

In infants with significant pulmonary hypoplasia who require ECMO, distending the lung with perfluorochemical in experimental protocols may promote lung growth.

Although early postnatal corrective surgery was advocated in the past, there has been a more recent shift toward delayed repair, in large measure because respiratory function often worsened in the immediate postoperative period. Consequently, early aggressive cardiorespiratory stabilization followed by delayed surgical plication is the recommended approach and is associated with improved outcome. An alternative to an initial period of attempted stabilization maybe an ex utero intrapartum therapy procedure (EXIT), in which the delivering fetus is orally intubated and placed on mechanical ventilation prior to umbilical cord ligation. In this approach, a brief trial of ventilation may be given; if oxygen saturation does not improve during the trial, the fetus is cannulated and ECMO (EXIT to ECMO) is initiated, followed by delivery of the infant. The validity of this approach remains unproved.

Surviving children with CDH may have brain injury, neurodevelopmental disability, hearing loss, feeding difficulties, gastroesophageal reflux, lung disease, scoliosis, and recurrence after repair.[70] In patients who required ECMO, 35% had brain abnormalities assessed by computed tomography (CT), and 35% to 45% needed a hearing aid.[71-73] Perhaps the most successful advance since the 1990s has been improvement in postnatal treatment to preserve and protect lung parenchyma using gentler ventilatory strategies.

Congenital Pulmonary Airway Malformation

Congenital pulmonary airway malformation (CPAM), previously known as

congenital cystic adenomatoid malformation (CCAM), is a relatively infrequent lesion, estimated to occur in 1 in 10,000 pregnancies.[74,75] CPAM is a discrete nonfunctioning, intrapulmonary mass characterized by overgrowth of terminal respiratory bronchioles that form cysts ranging from <1 mm to >10 cm. These cysts suppress alveolar growth and can communicate with the tracheobronchial tree, evidenced by air trapping seen after postnatal resuscitation. Cysts may also communicate with each other. Histologically, the lesions are notable for a preponderance of elastic tissue and for an absence of cartilage. The cysts are usually multiple, and in more than 95% of cases the cystic malformations lie within a single lobe. No single lobar predilection exists. A contributory gene influencing CPAM development is HOXB5[76]; its expression is maintained at a level typical of early lung development. Other growth and maturational factors including FGF7, KGF, and FGF10 have been implicated.

CPAMs are often divided into three types, which vary in anatomic and clinical characteristics according to the Stocker classification scheme.[77] A revised classification has added two new types, type 0 and type 4. Type 0 is bronchial dysplasia, and type 4 is the peripheral form of CPAM.[78,79] Type 1 CPAM, which accounts for about half of cases, occurs as a few large (>2 cm) cysts, usually one to four in number, or as a single large cyst surrounded by much smaller *satellite* cysts. Type 2 CPAM, which accounts for about 40% to 45% of cases, consists of multiple, small (<2 cm), evenly spaced cysts scattered throughout the affected area. Compared with type 1 CPAM, type 2 cysts are associated with a much higher incidence (about 25%) of anomalies in other organs, particularly in the genitourinary tract (eg, renal dysgenesis). Type 3 CPAM, which accounts for fewer than 10% of cases, occurs as large collections of tiny cysts; the affected area can be large, and this type often leads to early cardiovascular compromise, resulting in fetal hydrops or immediate postnatal complications. In the alveolo-acinar type of CPAM, small cysts are formed later in development, and in the bronchial epithelial type, larger cysts are formed early in the pseudoglandular phase of development.

Depending on the type, CPAM presents during the neonatal period in 50% to 85% of infants, but presentation may be delayed for up to several years. Cases are occasionally discovered incidentally. Lesions may be detected prenatally during routine sonography.

The most common presentation of CPAM is respiratory distress that results from obstruction, although infection of the cyst leading to recurrent lobar pneumonias can also occur. The elastic walls of the cyst allow easy expansion on inspiration, but the lack of cartilaginous support results in premature closure during exhalation and a ball-valve type of respiratory compromise.

Chest radiograph findings are variable and depend on the type of CPAM. In the neonate, a solid space-occupying mass will appear, becoming air filled over the next several hours or days. In types 1 and 2, multiple air-filled cysts may become evident. This appearance may be confused with diaphragmatic hernia. Placement of a nasogastric tube to determine the location of the stomach and intestines as well as the absence of a scaphoid abdomen helps distinguish between the two entities. The multiple small cysts of type 3 CPAM cannot be delineated on a chest radiograph. In this case, a CT scan of the chest can be helpful.

Treatment of symptomatic infants may require positive pressure ventilation. In some infants, PEEP may facilitate emptying of the cysts. Definitive treatment is

surgical removal of the affected lobe, which can often be performed thoracoscopically. Even if an infant is asymptomatic, surgical resection is recommended by 3 to 6 months of age because of the high risk of expansion or infection if the cysts are left untreated.

Prognosis depends on the type and extent of the CPAM. The large type 3 lesions are more likely to cause immediate respiratory distress and have higher mortality, especially if associated with pulmonary hypoplasia or fetal hydrops. The prognosis in type 2 CPAM depends on the presence and nature of associated anomalies.[80,81] In addition, malignant transformation of CPAM (mucinous adenocarcinoma) has been reported.[82,83] Most cases of CPAM, however, have a good prognosis.

A CPAM volume ratio (CVR) may be measured prenatally by sonography. An index of length × width × height × 0.52 that exceeds 1.6 at initial diagnosis predicts an increased risk for fetal hydrops.[81] Maternal prenatal glucocorticoid treatment increases survival rates and favors the resolution of hydrops in some cases. Fetal lobectomy has been performed after failure of glucocorticoid therapy in large lesions; EXIT procedures with lobectomy (EXIT to resection) while on placental circulation have also been attempted.

Bronchogenic Cysts

Bronchogenic cysts are rare[84] and occur as a result of anomalous budding of the ventral or tracheal diverticulum of the foregut during the 6th week of gestation, with subsequent separation from the normally developing bronchi by the 16th week of gestation. If separation occurs early (<12 weeks), the bronchogenic cyst tends to be located in the mediastinum (the most common type); if separation occurs later, it is more likely to be located in the peripheral pulmonary parenchyma. The cyst walls are cartilaginous and receive either systemic or pulmonary blood supply, depending on location.[85] Bronchogenic cysts are more common in male infants, are usually singular, are more commonly right sided, and are generally under 10 cm in diameter. These lesions generally do not communicate with the airway and remain fluid filled, which differentiates them from pulmonary parenchymal cysts.

Bronchogenic cysts generally do not present in the neonatal period unless they are large, expand rapidly, or are located near major airways; in these instances, infants may show moderate to severe respiratory distress. More commonly, the young child will have recurring episodes of wheezing or infection. Occasionally, asymptomatic bronchogenic cysts are visualized on chest radiographs taken for other reasons. Chest radiographs can readily reveal most bronchogenic cysts. The cyst typically appears as a round or oval water density mass, commonly in the mediastinal or perihilar area. If the cyst has become infected, an air-fluid level may be present.

Mediastinal bronchogenic cysts usually appear immediately inferior to the carina and extend to the right. Pulmonary bronchogenic cysts are usually sharply circumscribed and are located near the periphery. Two-thirds of these cysts are located in the lower lobes and show no right or left predilection. About 25% of bronchogenic cysts may be difficult to visualize with a chest radiograph. In these cases, CT scan can delineate the lesion and determine associated anomalies, such as a pulmonary sequestration.

Treatment may require ventilatory support for infants with respiratory distress. In all cases, surgical resection is indicated.[86] The prognosis for infants who have a

bronchogenic cyst, whether mediastinal or pulmonary, is good.[87]

Pulmonary Parenchymal Cysts

Pulmonary parenchymal cysts may represent a disorder of bronchial growth, although they may alternatively be acquired. Like adenomatoid malformations and bronchogenic cysts, congenital cysts arise early in fetal life. Pulmonary parenchymal cysts are thought to develop when completion of the terminal bronchioles and development of the alveoli occurs. Pulmonary cysts are typically thin walled, singular, multilocular, and located in the periphery. Unlike bronchogenic cysts, some communication usually exists between the pulmonary cyst and the tracheobronchial tree, so approximately 75% fill with air.

Like adenomatoid malformations, pulmonary cysts contain mostly elastic tissue and little or no cartilage. Although pulmonary cysts are generally small (1 to 2 cm in diameter), they can expand dramatically and are much more likely to cause respiratory insufficiency than are bronchogenic cysts. As in adenomatoid malformations, an absence of cartilaginous support leads to trapping of air. But unlike adenomatoid malformations, pulmonary cysts are rarely associated with other anomalies. Rupture of a peripheral cyst can result in a pneumothorax. Rarely, multiple cysts occur, and they may extensively involve both lungs. These cases are generally fatal within the perinatal period.

Chest radiographs typically reveal thin-walled, round cysts with an air density. Often, faint strands of lung tissue can be seen within the cysts. A large pulmonary cyst may be confused with congenital lobar emphysema. In this circumstance, a CT scan can easily distinguish the cystic nature of the former condition. Bronchogenic cysts are identified prenatally in 70% of cases using high-resolution ultrasonography. Reports of spontaneous resolution of pulmonary cysts have been infrequent. As with other cystic lesions of the lung, surgical resection of the affected lobe is usually indicated.

Pulmonary Sequestrations

Like bronchogenic cysts, pulmonary sequestrations result from an abnormal budding of the foregut, which retains its embryonic systemic arterial connections. Thus a sequestration is a mass of nonfunctioning, ectopic pulmonary tissue that has its own (systemic) blood supply. Sequestrations do not communicate with the trachea-bronchial tree.[88]

There are two types of pulmonary sequestrations, which are histologically similar. Extralobar sequestrations are surrounded by a separate pleura, whereas intralobar sequestrations are surrounded by lung tissue and have no separate pleural covering. Extralobar sequestrations account for about 25% of cases, are more common (90%) on the left side, are more common in males (80%), and are usually located in a subpulmonic location. Extralobar sequestrations are commonly associated (50% to 60%) with other anomalies, including direct esophageal communication, bronchial atresia, colonic duplication, CPAM, pulmonary hypoplasia, and diaphragmatic hernia. Most cases of extralobar sequestration become apparent during infancy. Presentations range from fetal hydrops with massive pleural effusions or pulmonary hypoplasia to recurrent lower respiratory infections (particularly if a gastrointestinal

communication is present).

Intralobar sequestrations are the more common type (75%). They are usually left sided (65% to 70%) and typically occur in the lower lobes. Unlike extralobar sequestrations, they are rarely associated with other anomalies. Most cases are asymptomatic and are discovered on chest radiographs obtained for other reasons. Symptomatic cases typically present in late childhood with recurrent infections. Distinguishing between extralobar and intralobar sequestrations on chest radiographs may be difficult. Both lesions can appear as either solid or cystic structures, although extralobar lesions are more often solid and intralobar lesions are more often cystic. Delineation of the vascular supply to the sequestration is important to differentiate extralobar sequestrations from CPAMs and to guide surgical management. Magnetic resonance imaging has replaced arteriography for obtaining this information. Some authors recommend a study of the GI tract, particularly if communication with the sequestration is suspected. As with other cystic lesions of the lung, surgical removal is indicated and may be done thoracoscopically. Whereas extralobar sequestrations can be removed en bloc because of their separate pleural covering, intralobar sequestrations require lobectomy. Partial success with a nonsurgical approach using transumbilical artery embolization during the newborn period has been reported.

Congenital Lobar Emphysema

Congenital lobar emphysema is an unusual disorder characterized by progressive lobar overdistention of the lung as a consequence of developmental disruptions.[77,89,90] Other terms include *congenital lobar overinflation* and *infantile lobar emphysema,* although the term *overinflation* may be a misnomer.

In fewer than 25% of cases, clinical and radiographic findings are typical of a ball-valve type of obstruction. More commonly, the cause for air trapping remains uncertain.[91] Intrinsic bronchial obstruction may result from a deficiency of cartilaginous support or an intraluminal mass such as a mucous plug. Extrinsic bronchial obstruction usually results from an underlying cardiovascular abnormality, such as a vascular sling or, rarely, a PDA. An intrathoracic mass, such as an enlarged lymph node or a bronchogenic cyst, also can cause extrinsic obstruction.

Congenital lobar emphysema is more common in male infants[90] and typically occurs in the upper lobes or the right middle lobe. Fewer than 1% of cases occur in the lower lobes. Up to 20% of the cases show bilateral involvement. Associated cardiovascular anomalies are common. Rib cage anomalies and aplasia/dysplasia of the kidneys have been reported in a small percentage of cases. In most infants with congenital lobar emphysema, the condition presents within the first month of life, and about one-third of infants exhibit respiratory signs within hours of birth. Respiratory compromise is directly related to the degree of overinflation. Typically, infants have mild to moderate tachypnea, asymmetric inflation of the chest, and cyanosis. A chest radiograph reveals the overinflated lobe with ipsilateral atelectasis and flattening of the hemidiaphragm; mediastinal shift away from the affected side may be observed. A CT scan may help to identify the cause of obstruction, if one is present. Lobectomy is the definitive treatment and may be performed thoracoscopically. Surgery is limited to symptomatic cases. Favorable outcomes are

reported in asymptomatic or minimally symptomatic cases in which surgery was not performed.[92]

Pulmonary Agenesis and Aplasia

Pulmonary agenesis and aplasia are rare, highly lethal disorders with similar underlying causes that differ from causes of pulmonary hypoplasia. Pulmonary agenesis and aplasia result from an arrested development of the embryonic lung. The earlier in development arrest occurs, the more severe the defect. In pulmonary agenesis, the bronchial tree, pulmonary parenchyma, or pulmonary vasculature does not develop. In pulmonary aplasia there is a rudimentary bronchial pouch.

The resulting lesions may involve one lobe or the entire lung. Focal or bilateral defects are rare. Pulmonary agenesis or aplasia may be associated with other nonpulmonary anomalies including microphthalmia/anophthalmia, cleft palate, cardiac defects, congenital diaphragmatic hernia/eventration, and limb abnormalities. Abnormal blood flow in the dorsal aortic arch during the 4th week of gestation has been hypothesized to cause pulmonary agenesis. The contralateral lung may develop as many as twofold more alveoli in response to pulmonary aplasia/agenesis.

The clinical presentation is variable. If the defect is focal and isolated, the infant may have normal respirations, though mild respiratory distress may be present. A chest radiograph reveals unilateral lung or lobar collapse with a shift of mediastinal structures, which leads to a suspicion of bronchial or bronchiolar obstruction. Misdiagnosis may subject the infant to unnecessary risks of bronchoscopy despite CT being readily available for diagnosis. Associated anomalies of the cardiovascular, gastrointestinal, genitourinary, central nervous, and musculoskeletal systems have all been described. If the defect is isolated to a single lobe, surgical resection will reduce respiratory signs and lower the risk for infection. If the defect is extensive but the fetus is potentially viable, an ex utero intrapartum procedure may be attempted.

Prognosis depends on the degree of pulmonary involvement, whether or not there have been recurrent pulmonary infections, and the presence of associated anomalies. Bilateral defects are invariably lethal. If the defect is focal, the remaining normal lung undergoes compensatory hypertrophy. Nevertheless, mortality exceeds 50%, generally because of the presence of associated malformations. Right-sided defects have a poorer prognosis than left-sided lesions, partly because of a higher association with other anomalies and partly because of an increased risk for disseminating infection. Right-sided lesions also may produce a more severe mediastinal shift, distorting the trachea and great vessels. Repeated lower respiratory infections can result in progressive pulmonary debilitation and increase the risk of death.

Special Treatment Considerations for Acute Respiratory Failure

Surfactant Replacement

Exogenous surfactant therapy has significantly decreased the incidence, severity, and morbidity of RDS and improved the survival of low-birth-weight infants.

Exogenous surfactants in current clinical use are considered natural because they are derived from either bovine or porcine lungs. Newer synthetic forms of surfactant that incorporate recombinant human proteins are increasingly available. Both natural and synthetic surfactant extracts are effective in the prevention and treatment of respiratory distress syndrome. A meta-analysis showed natural surfactant demonstrates greater early improvement in the requirement for ventilator support, lower incidence of pneumothorax, and risk of mortality when compared to earlier generations of synthetic surfactant. Human surfactant, purified and concentrated from pooled amniotic fluid, has also been studied clinically and is effective, but it is not generally in use. The three commercial animal-derived surfactants are compositionally different from one other, even though two use the same animal species source. These differences are, in large part, due to the methods by which the surface-active components are extracted or supplemented in the different preparations. Although most compositional differences have little biophysical or clinical importance, differences in SP-B content appear to affect onset and duration of activity and resistance to inhibition.

Conditions such as meconium aspiration, persistent pulmonary hypertension, hemorrhagic pulmonary edema, congenital diaphragmatic hernia, pulmonary hypoplasia, acute respiratory distress syndrome (ARDS), pneumonia, bronchiolitis, and asthma are associated with surfactant dysfunction and inactivation so that persons with these conditions might also benefit from exogenous surfactant therapy.

High-Frequency Ventilation

Two types of high-frequency ventilation (HFV) are commonly available for use in neonates. One type (Bunnell Life Pulse) uses a highly pressurized, intermittent jet of gas delivered at rates of 120 to 600 Hz and is called high-frequency jet ventilation (HFJV). The other type (Sensormedics Oscillator) uses an oscillating diaphragm or piston to provide active instillation and withdrawal of gas and is called high-frequency oscillatory ventilation (HFOV).

Although the effects of ventilator settings have been well studied in HFV, the actual mechanics of gas exchange during HFV are less well understood. Similar to conventional rate ventilation, oxygenation is affected primarily by inspired oxygen concentration and mean airway pressure. Although ventilation is affected by both volume and frequency, the effect of volume is much more pronounced than during conventional rate ventilation, and the effect of frequency is contrary to what might be expected because the frequency inversely affects tidal volume. In practice, frequency is not a critical variable within the ranges afforded by high-frequency ventilators and is not a principal adjustment during HFV use. One key advantage to HFV use in the neonate is the capability for using high-end expiratory pressures without the need for high-inspiratory pressures in order to maintain normal tidal volumes. This feature permits the adjustment of mean airway pressure more or less independent of volume. This ability is particularly desirable when significant V/Q mismatch exists, such as in the neonate who has idiopathic persistent pulmonary hypertension and whose lungs may be easy to ventilate but who is marginally oxygenated with 100% oxygen. Another advantage of HFV is the ability to use low, usually subphysiologic tidal volumes. The use of low volumes prevents alveolar overdistention and rupture of more compliant alveoli, thereby reducing the risk of

pneumothorax. Furthermore, HFV reduces airflow across existing air leaks, potentially promoting their closure and facilitating more effective ventilation in situations such as severe PIE or bronchopleural fistula. Nevertheless, a specific advantage of HFV over conventional volume-triggered or pressure ventilation in preterm infants with RDS, other than managing air leaks, has not been demonstrated.

Complications reported with HFV use include hypotension (more commonly with HFOV), pulmonary hypertension, tracheobronchitis, and, in preterm infants, intraventricular hemorrhage. Because use of excessive airway pressures may impede cardiac return and increase pulmonary vascular resistance, hyperinflation should be avoided. Necrotizing tracheobronchitis, which was seen in the early years of HFV, is now rare, in part due to attention to humidification and avoidance of excessive mean airway pressures. Although some studies have suggested very low-birth-weight (less than 1500 g) infants treated early with HFOV may have a lower incidence of chronic lung disease, others have suggested that HFOV increases the risk of intracranial hemorrhage in preterm infants, perhaps because of altered cerebral blood flow and drainage. Other clinical studies have found no such association. Animal studies have found significant effects of HFV compared to conventional rates ventilation on the cerebral circulation.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) evolved from cardiac bypass technology with the introduction of membrane oxygenators that operate for days without significantly disrupting blood cells and plasma proteins. However, when applied to premature neonates with RDS, ECMO initially was disappointing. ECMO did not reduce mortality rates in patients with ARDS and was associated with a high risk of intracranial hemorrhage in preterm infants. Nevertheless, subsequent use of ECMO in term infants with cardiorespiratory failure, particularly those with persistent pulmonary hypertension and congenital diaphragmatic hernia for whom conventional therapies had failed, has led to its increasing neonatal application, despite the absence of controlled clinical trials. In neonates with respiratory failure, compared with other indications for ECMO, respiratory syncytial virus (RSV)/lower airway disease has a far higher survival rate (96%) and a very low rate of neurologic sequelae.

Most causes of neonatal respiratory failure in the newborn are self-limited, and ECMO allows time for lung recovery from the underlying disease process and for reversal of pulmonary hypertension, which frequently accompanies respiratory failure in the newborn.

Nitric Oxide Inhalation

In mammals, vascular smooth muscle relaxation is, in part, regulated by nitric oxide, which is released by adjacent endothelial cells in response to flow and shear stimuli and stimulates guanylate cyclase to produce the potent vasodilator, cyclic guanosine monophosphate. Inhaled nitric oxide causes significant pulmonary vasorelaxation without exerting significant systemic effects because it is rapidly scavenged by hemoglobin in the pulmonary microvascular circulation. Inhaled nitric oxide reaches

and selectively vasodilates lung units that are better ventilated, thereby optimizing ventilation-perfusion matching. Inhaled nitric oxide is approved for use in term and near-term (≥34 weeks' gestation) infants who have persistent pulmonary hypertension. Although it does not alter the long-term outcome in patients with this condition, it significantly reduces the need for rescue treatment with ECMO.[93]

Although nitric oxide inhalation has received much interest in the management of term infants with persistent pulmonary hypertension, other applications remain under evaluation. Animal studies suggest nitric oxide may have a significant role in the successful perinatal transition to air breathing. Clinical studies suggest inhaled nitric oxide may be beneficial in infants with surfactant-deficient RDS, particularly those who do not respond to exogenous surfactant therapy. The basis for these applications is the observation that pulmonary hypertension also occurs in preterm infants with RDS. In preterm animal studies, nitric oxide production modulates basal pulmonary vascular tone.

Rare clinical complications of inhaled nitric oxide include methemoglobinemia (because of the high affinity for hemoglobin) and prolonged bleeding times. The toxicity of nitric oxide metabolites includes the potential for injury to the pulmonary epithelium and surfactant system.

Liquid Ventilation

Liquid ventilation with perfluorochemicals, in a complete departure from traditional ventilation with gases, is an alternative ventilatory strategy that has received interest especially in adult critical care. Specific advantages of liquid instead of gas expansion of the lungs were first demonstrated in the 1920s, but application to the clinical setting was hampered by the poor solubility of most liquids for oxygen and carbon dioxide and technical difficulties in achieving liquid tidal volume exchange. The introduction of perfluorochemicals, which have high solubility for respiratory gases, and development of specific liquid ventilators enabled researchers to study liquid ventilation in animals in the 1970s. The demonstration that complete tidal liquid movement was not necessary to capitalize on the advantages of liquid ventilation made liquid ventilation a clinical reality in the 1990s.

Partial liquid ventilation (PAGE, PFC (perfluorocarbon)-associated gas exchange) is the term applied to conventional gas tidal volume ventilation superimposed on liquid-filled alveoli (ie, alveoli filled to functional residual capacity). Although, in animal studies, gas exchange can be impaired by too rapid liquid ventilation in the healthy lung, it is improved in many injured lung models. Possible mechanisms for this improvement include reducing surface tension and maintaining alveolar stability, thereby eliminating the need for alveolar surfactant by filling the alveoli with liquid and removing the air-liquid interface normally present.

Perfluorochemicals also may produce a mechanical PEEP, holding the alveoli open because of the higher liquid density. Consequently, partial liquid ventilation may offer the potential to manage infants with respiratory distress resulting from surfactant deficiency or dysfunction, for whom exogenous surfactant replacement has failed or becomes impractical (eg, those with a heterogeneous lung disease such as ARDS). In animal models, perfluorochemicals also reduce neutrophil accumulation and the inflammatory response to lung injury, and they inhibit hydrogen peroxide and free radical production by macrophages. Studies in animals

also show partial liquid ventilation leads to a marked improvement in respiratory mechanics compared with conventional ventilation strategies.

Large randomized human trials have been limited by the dose-dependent risk of hypoxia and barotrauma associated with perfluorocarbon.[94,95] No studies of perfluorochemical liquid ventilation have been conducted in term neonates with respiratory disease. Current information is limited to clinical trials and individual case reports.

Chronic Pulmonary Disease

Chronic Lung Disease (Bronchopulmonary Dysplasia)

The classical phenotype of bronchopulmonary dysplasia (BPD) of severe alveolar septal fibrosis and cavitation, first described by Northway and coworkers,[96] is less commonly seen in the postsurfactant era. A milder form of BPD *(new BPD)* is associated with disruption of lung development, specifically in extremely preterm infants, an arrest of alveolar septation, and vascular development in the distal part of the lung leading to impaired pulmonary function in later life. Microvascular disruption has marked angiogenesis proportionate to the growth of air-exchanging lung parenchyma. Prominent corner vessels with variable capillary density in adjacent alveoli or vessels most distant from the air surface are prominent features of this new BPD.[97-99] The reported incidence of BPD in infants born at less than 28 weeks' gestation varies between 15% and 50% and increases with earlier gestational age.[100]

The changing spectrum of BPD has led to multiple revisions in the definition. A National Institutes of Health consensus meeting in 2001 proposed new criteria based on supplemental oxygen requirement and severity (Table 54.1).

TABLE 54.1

Diagnostic Criteria for Bronchopulmonary Dysplasia: National Institutes of Health, 2001

	Mild Supplemental O_2 for 28 Days and	**Moderate** Supplemental O_2 for 28 Days and	**Severe** Supplemental O_2 for 28 Days and
<32 weeks GA at birth	RA at 36 weeks corrected GA or at discharge	<0.3 FiO_2 at 36 weeks corrected GA or at discharge	≥0.3 FiO_2 at 36 weeks corrected GA or at discharge
≥32 weeks GA at birth	RA by postnatal day 56 or at discharge	<0.3 FiO_2 by postnatal day 56 or at discharge	≥0.3 FiO_2 by postnatal day 56 or at discharge

GA, gestational age; *RA*, room air.

The pathogenesis of BPD involves prolonged injury and repair in the immature lung. Imbalance in the release of pro- and antiinflammatory cytokines results from volu/barotrauma, hyperoxia, pulmonary edema, and sometimes superimposed infection. The inflammatory and repair responses are modulated by genetic susceptibilities.

The association of mechanical ventilation and oxygen therapy with BPD has been demonstrated in multiple animal models. In preterm lambs, chronic ventilation with less than 30% oxygen can produce BPD-like pulmonary changes. These observations

have led to the postulate that even room air might be hyperoxic to the very preterm human lung. The preterm human lung has low FRC and total lung capacity and may require airway pressures >20 cm H_2O to maximally recruit lung volume. The lung volume available between FRC and TLC for safe mechanical ventilation may be as low as 15 ml/kg (50 ml/kg for term infants). Injury can occur during neonatal resuscitation because of the physiologic difficulties of establishing an FRC while avoiding overdistention of the lung. During the urgent interventions to ventilate a distressed newborn, overly aggressive ventilation can promote excessive lung volumes.

Animal models have characterized ranges of fetal lung responses to inflammatory exposures. Mediators of epithelial lung injury include proinflammatory cytokines, including interleukin-1β (IL-1β), IL-6, IL-8, and tumor necrosis factor (TNF)-α,[101-103] and impaired signaling of growth factors such as vascular endothelial growth factor (VEGF).[104,105] Antenatal inflammation potentiates postnatal inflammatory pathways. Most extremely low-birth-weight (ELBW) infants are exposed to antenatal corticosteroids and many may be exposed to chorioamnionitis. Ureaplasma species are frequently associated with BPD. Additional risk factors include maternal infection, neonatal sepsis, and PDA.

Although better monitoring, improved ventilation strategies, and new technologies have helped to reduce the incidence and severity of BPD in more mature neonates, increased survival of ELBW infants has increased the overall prevalence of this condition in NICU graduates.

The clinical presentation of BPD depends on the severity and extent of the acute lung injury. In the most severe cases, infants may require a considerable ventilatory and oxygen support beyond the age of 1 week. These infants are slow to wean from mechanical ventilation, require supplemental oxygen for weeks to months, and have episodes of bronchospasm or desaturation. Infants with severe BPD can exhibit varying degrees of right ventricular failure or, in less severe cases, simply display fluid intolerance. In the less severe and more common instances, onset is more insidious. For the first 2 to 3 weeks of life, these ELBW infants may appear stable on minimal ventilatory and oxygen support, but the need for increased ventilatory and oxygen support slowly develops. These infants often have episodes of apnea, desaturation, or carbon dioxide retention. Increased secretions from the endotracheal tube may occur. The chest radiograph may show areas of atelectasis, but more commonly the lung fields appear clear in the early stages or show minimal, homogeneous increased lung field density. Depending on clinical signs, confounding conditions such as a PDA, pneumonia, or aspiration must be considered.

The goal of management is to promote lung growth while supporting respiratory needs and minimizing further lung injury by preventing oxygen toxicity (and ensuing pulmonary hypertension and complications) and ventilator-induced lung injury (VILI). Guides for pressure-cycled mechanical ventilation include short inspiratory times (0.24-0.4 sec), rapid rate (40-60/min), low PiP (14-20 cm H_2O), moderate PEEP (4-6 cm H_2O), and low tidal volume (3-6 ml/kg). Bronchodilators may be helpful, particularly during exacerbations, due to the large airway component in BPD. Fluid restriction or diuretics may be helpful in infants who have evidence of cor pulmonale or fluid intolerance. At initial presentation, infants often

receive antibiotics until infection is ruled out. Infants with pulmonary insufficiency have increased energy needs, making nutritional support particularly important.

An approach aimed at reducing the inflammation and ongoing fibrotic injury has included the use of glucocorticoids. Dexamethasone has been shown to be effective in weaning off mechanical ventilation when used moderately early and delayed.[106-110] However, early use (<4 days) is associated with neurologic sequelae.[111] Postnatal steroid courses to improve BPD remain controversial. Infants who receive long courses of steroids for BPD usually show biochemical evidence of adrenal suppression, which may last for several months. Inhaled steroids offer no advantage over the intravenous route, aside from ease of administration.

New therapies to prevent or reduce the severity of BPD have been studied. Antioxidants like *N*-acetyl cysteine and recombinant superoxide dismutase (rSOD) have not shown decreases in BPD. Vitamin A has improved septation and alveolar capillary growth in animal studies and modestly decreased BPD rates in clinical studies.[112] Nitric oxide and high-frequency ventilation have protective effects in animal models but have not consistently shown benefit in several clinical trials. Antiproteases and thyrotropin-releasing hormone also have shown mild protective effects in animal models.[113-117]

Preconditioning is a concept in which antenatal exposures modulate postnatal experience.[118] When mice were exposed to intraamniotic lipopolysaccharide (LPS), a BPD-like phenotype was exhibited in newborn mice.[119] Postnatal exposure to >95% oxygen increases BPD-like abnormalities, but postnatal exposure to 65% oxygen has had the opposite effect of accelerated lung growth and attenuated pulmonary hypertension. In sum, antenatal inflammation can cause the BPD phenotype to be substantially modified.

Animal experiments have suggested promising lung protection and regeneration strategies using mesenchymal stem cells (MSCs) or progenitor cells from the endothelial lineage in experimental animal models. In a small phase 1 clinical trial involving nine infants between 23 and 29 weeks' gestation, a single intratracheal transplantation of MSCs derived from human umbilical cord cells was associated with a reduction in the severity of BPD and had no reported adverse effects.[120] Another mechanism contributing to the long-term efficacy of MSCs may be the transfer of mitochondria from MSCs to damaged lung cells.

The long-term outcome for infants with classic BPD has improved over the years, although these infants remain at risk for significant morbidity and mortality. VLBW infants with BPD have greater impairment of fine and gross motor skills and language and cognitive skills than infants without BPD.[121,122]

Infants who have BPD may require supplemental oxygen for the first several months of life, and some may require chronic diuretic and bronchodilator therapy. High-caloric formulas should be considered for infants who cannot tolerate fluid loading. Rehospitalizations may occur as a result of respiratory exacerbations, often brought on by infection, during the first 2 years of life.[123] These infants are also at risk for sudden death due to pulmonary hypertension or bronchospasm.

Mortality from BPD has markedly improved, but it remains high in infants with complicating conditions such as cardiovascular disease or in those who have intercurrent respiratory infections, particularly RSV or adenovirus. Passive immunization against RSV is recommended for high-risk premature neonates but it is not uniformly protective. Minimizing exposure to environmental hazards,

whether infectious or irritant (eg, from kerosene burners or cigarette smoke), cannot be overemphasized.

Congenital Defects of the Lymphatics

Congenital chylothorax is thought to result from a failure of peripheral and central lymphatic channels to fuse or, perhaps, from a rupture of inadequately fused channels at birth. The congenital condition has a different course and prognosis from postoperatively acquired chylothorax. Most affected infants show respiratory signs within hours from birth and may require mechanical ventilation. Congenital chylothorax may be associated with chromosomal abnormalities or other malformations, as described in a case series of 11 newborns. Familial cases are especially common in babies with associated congenital pulmonary lymphangiectasis with bilateral chylothoraces.

Progressive respiratory compromise develops as fluid accumulates in the hemithorax. Pleural drainage is both diagnostic and therapeutic. Initially, the lymphocyte-rich fluid is clear, but it becomes opaque when milk feedings are introduced. Nutritional support is critical because of a loss of protein in the chylous drainage. Most cases spontaneously resolve in 2 to 3 weeks. Occasionally, a several-day course of a somatostatin analog, which reduces chyle flow, or surgical closure of the thoracic duct is indicated.[124] Whether congenital or postoperative, common chylothorax complications include nosocomial infection, hemodynamic disturbance, and protein loss.

In the congenital form, time to resolution is significantly affected by additional underlying problems. Pulmonary lymphangiectasia is a rare condition that can be a primary or due to secondary dilation of pulmonary lymphatics from obstructed pulmonary venous flow. Primary lymphangiectasia can be isolated, termed *congenital pulmonary lymphangiectasia,* or it can be part of a generalized condition that includes intestinal lymphangiectasia, in which pulmonary involvement is less severe. Congenital pulmonary lymphangiectasia may result from the failure of connective tissue elements to regress during fetal lung development. In some cases, a hereditary pattern has been suggested. Affected infants usually show respiratory signs soon after birth. However, some infants may remain symptom free for several weeks. Affected infants are usually born at term and may have a normal examination except for mild tachypnea, they may be more severely affected with cyanosis, or they may be frankly hydropic. Preterm infants may be mistaken as having surfactant-deficient RDS. Radiographs generally reveal streaky reticular densities as a result of engorged lymphatics, and occasionally a finer, ground-glass appearance may be confused with surfactant deficiency.

Pleural effusions have been reported but are unusual. The condition is progressive and untreatable. Most infants die within days, but occasional survivors beyond infancy have been reported.

Lymphatic dysplasias, formerly termed *cystic hygromas (CHs),* are cystic lymphatic lesions that can affect many anatomic sites. These lesions usually occur in the head and neck (~75%), with a predilection for the posterior triangle on the left side. Less common sites include the axilla (20%), mediastinum, groin, and retroperitoneum.[125] Other terms, including *lymphangioma, cavernous lymphangioma, cystic lymphangioma,* and *lymphangioma circumscriptum,* have been abandoned due to confusion with and

absence of risk for malignant transformation.

Nonpulmonary Conditions That Result in Respiratory Disease

Many nonpulmonary disorders may present with respiratory distress in the neonate (Table 54.2). Conditions that affect the control or mechanics of breathing, patency or integrity of the upper airway, perfusion to and from the lung, or acid-base balance can present with increased respiratory effort or signs of respiratory insufficiency (ie, respiratory acidosis or hypoxemia).

TABLE 54.2

Nonpulmonary Conditions That Cause Respiratory Distress in the Newborn

Disorders of Respiratory Control
• Central hypoventilation disorder • Apnea
Airway Obstruction/Patency
• Choanal stenosis/atresia • Mandibular hypoplasia/micrognathia • Laryngomalacia • Laryngeal web/stenosis • Vocal cord injury • Airway vascular tumors/malformations • Tracheobronchomalacia • Tracheoesophageal fistula • Vascular compression
Interference With Respiratory Mechanics
• Neuromuscular disorders • Phrenic nerve injury • Eventration of the diaphragm • Pleural effusion • Chest wall anomalies
Perfusion Abnormalities
• Persistent pulmonary hypertension of the newborn • Hyperviscosity • Congenital heart disease
Disorders of Acid-Base Balance
• Metabolic disorders (eg, organic acidemias) • Intestinal bicarbonate wasting • Renal bicarbonate wasting • Sepsis • Iatrogenic metabolic acidosis/alkalosis

The clinical and radiographic picture may be consistent with an underlying pulmonary pathologic condition, but nonpulmonary causes should be considered, particularly if an infant is gravely ill or does not respond to conventional treatments. In many nonpulmonary conditions, a delay in diagnosis can lead to progressive injury and death.

Neonatal Apnea

Apnea is one of the most common respiratory problems encountered in the neonatal population. The incidence of apnea is inversely proportional to gestational age at birth, and more than 75% of infants born before 27 weeks will have apnea at some point during their hospital stay. For infants born at 30 to 31 weeks, the risk is approximately 50%, and for those born at 32 to 33 weeks, the risk is about 14%. The

risk for those born at 34 to 35 weeks is 7%. Apnea can be broadly classified as physiologic (ie, apnea of prematurity) or pathologic (ie, resulting from an underlying disorder such as sepsis). The American Academy of Pediatrics has defined apnea as "an unexplained episode of cessation of breathing for 20 seconds or longer, or a shorter respiratory pause associated with bradycardia, cyanosis, pallor, or marked hypotonia."

Apnea can be classified into three main types. The first is central apnea, which results from decreased/altered central responsiveness to respiratory stimuli, such as hypoxia and hypercarbia. Responsiveness improves as the infant matures and approaches term gestation. This type of apnea is characterized by cessation of respiratory effort, which usually occurs at the end of exhalation. The second type of apnea is obstructive apnea due to anatomic or physiologic restriction of the airway. Common examples include tracheomalacia and Pierre Robin sequence. The respiratory pattern of obstructive apnea demonstrates increasing respiratory effort with little to no air movement. Mixed apnea represents the third type of apnea. Initially, the infant may have a central apneic event, but when respiratory effort is made, an obstructive pattern is revealed.

The obstructive pattern is thought to result from gradual airway collapse during the initial central apneic portion of the episode. Most apneic episodes lasting longer than 20 seconds fall into this category.

Although apneic spells are a common cause of readmission following NICU discharge, apnea of prematurity remains a diagnosis of exclusion. Most infants who have apnea of prematurity achieve complete resolution of symptoms by 34 to 36 weeks, postconceptional age. Once apnea of prematurity has resolved, it does not return. Pathologic causes such as hypoglycemia, hypoxemia, hypothermia or hyperthermia, infection, left-to-right shunt, and intracranial hemorrhage should be ruled out. New-onset apnea in a previously symptom-free infant presents diagnostic concern. Apnea also increases in response to less stressful stimuli, such as immunizations or an ophthalmic examination. Apnea in a term or near-term infant is almost always pathologic. Isolated apnea may be treated with simple tactile stimulation in many cases. Infants who remain apneic after stimulation may require blow-by oxygen, nasal cannula therapy, nasal continuous positive airway pressure, nasal intermittent mechanical ventilation, or even reintubation and mechanical ventilation, depending on the severity, recurrence, and presence of underlying pathology.

Caffeine is the pharmacologic agent of choice to treat apnea because of its long plasma half-life and low toxicity. However, not every infant responds to caffeine therapy. One study identified genetic markers (adenosine receptor gene polymorphisms) that may predict an individual's response to caffeine. Studies show that 4% to 13% of sudden infant death syndrome (SIDS) cases have a history of apnea. However, multiple studies have failed to demonstrate a link between acute life-threatening events (ALTEs) and SIDS. More than 80% of SIDS cases occur between midnight and 6 am, whereas more than 80% of ALTEs occur between 8 am and 8 pm.

Choanal Atresia/Stenosis

Choanal obstruction resulting from a failure of bony or membranous regression is

the most common supralaryngeal congenital defect. It occurs in approximately 1 in 4000 live births. Choanal atresia is often associated with defects in other organs or with syndromes that include other craniofacial anomalies, especially CHARGE syndrome (*c*oloboma of the eye, *h*eart anomaly, choanal *a*tresia, *r*etardation, and *g*enital and *e*ar anomalies). Choanal atresia is usually unilateral, typically on the right side; a 2 : 1 excess of choanal atresia has been reported in girls. Unilateral choanal atresia occurs more frequently in isolated cases, whereas bilateral choanal atresia should prompt further evaluation for other congenital anomalies. Associated findings include a high-arched palate, thickening of the vomer, and medial bowing of the lateral wall of the nose. Clinical presentation depends on the degree of obstruction. Bilateral choanal atresia or severe bilateral stenosis becomes evident in the newborn period, whereas unilateral cases or mild stenosis may not present for weeks, months, or years. Infants who have respiratory signs typically are distressed during times of sleep or feeding, when nasal breathing predominates. Clinical presentation in infants with unilateral obstruction or mild stenosis may occur only when the nares become obstructed, as during the passage of a nasogastric tube or inflammation in an upper respiratory infection. With occlusion of the patent nares, an infant may suddenly decompensate with signs of severe respiratory distress.

Infants in severe distress may require elective intubation if an oral airway proves insufficient or cannot be easily maintained. Direct visualization of the obstruction is best performed by an otolaryngologist using a fiberoptic scope. A cranial CT scan can determine the presence and thickness of the bony plate within the nasal cavity, which is an important surgical consideration. Definitive treatment generally involves drilling through the bony plate and stenting the nasal passage with tubes for 6 weeks to allow proper healing. A high degree of suspicion is key to diagnosing and properly treating this disorder, and if true bilateral choanal atresia is present, associated anomalies must be excluded.

Laryngomalacia

Laryngomalacia is the most common cause of stridor in the neonate. It is a dynamic lesion resulting in collapse of the supraglottic structures during inspiration, leading to airway obstruction. Infants have an omega-shaped epiglottis (curled onto itself). Similar to infants with mandibular hypoplasia, infants with laryngomalacia tend to have more respiratory insufficiency in the supine position because it allows the relatively unsupported anterior tissue to drop into hypopharynx, causing obstruction. Affected infants may be stridulous during periods of crying or distress. Rarely, the lesion may cause sufficient hypoxemia or hypoventilation to interfere with normal growth and development. Treatment includes prone positioning, and resolution is common by age 1 to 2 years.

Vocal Cord Paralysis

Vocal cord paralysis may be unilateral or bilateral. Unilateral cord paralysis usually presents with a weak or sometimes hoarse cry. Obstructive signs, such as stridor or retractions, are less severe and less common. The infant may also cough or choke while feeding because of an inability to prevent aspiration while swallowing. Common causes are stretch injury during delivery or recurrent laryngeal nerve

injury during ductus ligation. Consequently, left-sided paralysis or paresis is most common. Respiratory signs from unilateral cord paralysis usually improve over several weeks or months without intervention but may take years to resolve.

Bilateral cord paralysis is a more serious problem and is often the result of an intracranial pathologic condition, such as Chiari malformation, intracranial hemorrhage, or hypoxic-ischemic encephalopathy. These infants may have near total airway obstruction and moderate to severe stridor. Many will require tracheostomy to maintain a stable and patent airway.

Airway Vascular Tumors/Malformations

Hemangiomas are the most common vascular tumors of the airway and occur in isolation or as part of a spectrum of posterior fossa malformation, arteriovenous malformations, cardiac/aortic defects, eye anomalies, and sternal defect (PHACES) syndrome. Congenital hemangiomas located just below the level of the vocal cords are another relatively uncommon cause of stridor in neonates, with or without expiratory wheeze. Hemangiomas often enlarge as the newborn grows and can threaten the airway. Positional changes tend to have little effect on the severity of respiratory signs. Superficial, capillary hemangiomas on the skin of the neck are often present, suggesting the diagnosis. For acute exacerbations, systemic and intralesional steroids are a mainstay of first-line therapy. For steroid unresponsive lesions, some evidence suggests antiangiogenic agents (IFN-α2a and IFN-α2b) may be effective. Anti-VEGF agents like bevacizumab are under evaluation. Nevertheless, symptomatic infants eventually may require surgical removal of the lesions. The availability of laser surgical ablation has markedly reduced the need for tracheostomy in children with subglottic hemangioma. Open excision has an estimated 90% success rate. Propranolol has had a beneficial role in the involution of hemangiomas.

Tracheobronchomalacia

Tracheobronchomalacia is characterized by an abnormally compliant airway cartilage, leading to intermittent airway collapse during normal respiration. Specific classification depends on the area(s) involved (eg, tracheomalacia, tracheobronchomalacia, and bronchomalacia). Infants may be mildly or severely affected, depending on the extent of involvement and the capacity of surrounding supporting tissues to maintain airway patency. Affected infants generally have respiratory signs in the newborn period, but presentation may be delayed for days or weeks if the defect is mild. In these milder cases, infants may remain free from respiratory distress until intercurrent infection leads to increased airway secretions and increased work of breathing. Signs include expiratory wheezing and respiratory distress including tachypnea and retractions, and the infant may receive a mistaken diagnosis of reactive airway disease. Paradoxically, the use of bronchodilators may actually worsen the condition. A chest radiograph may show hyperinflation.

Definitive diagnosis is made by direct visualization, typically with flexible tracheobronchoscopy. Treatment is supportive as airway compromise generally lessens as the infant grows. However, more severe cases may require stenting with continuous positive airway pressure or even surgical plication. Tracheostomy alone

may not be helpful if the affected area extends beyond the proximal trachea. A high association with other congenital anomalies, including vascular rings or tracheoesophageal fistula (discussed later in this chapter), also should be considered. A history of recurrent coughing or choking should prompt further investigation.

Tracheoesophageal Fistula

Esophageal atresia with tracheoesophageal fistula (TEF) occurs in approximately 1 in 4500 live births, making it one of the most common congenital malformations. Usually isolated, it can be associated with other anomalies including complex syndromes and malformation sequences such as VATER (vertebral defects, anal atresia, TEF, esophageal atresia, and renal anomalies), VACTERL (VATER plus cardiac and upper limb defects), and CHARGE (coloboma, heart defect, choanal atresia, mental retardation, genital hypoplasia, ear anomalies, and deafness). In the absence of a recognized syndrome, TEF may also be associated with isolated cardiac defects, present in up to 50% of cases. Whether as part of a syndrome or an isolated anomaly, TEF usually is associated with esophageal atresia; in 5% to 7% of cases there is no associated esophageal atresia (H-type TEF).

TEF and associated esophageal atresia and TEF as part of a more general disorder invariably present in the immediate newborn period. Infants with an isolated H-type fistula may remain clinically silent for many weeks or even months.

Although relatively rare (approximately 1 in 100,000 live births), an H-type fistula must be suspected in any infant who coughs during feedings and has recurrent pneumonitis. In preterm infants it can present as apnea spells with no other signs. The diagnosis of an H-type fistula can be difficult but is best discovered by a cine esophagram. In cases in which this study is inconclusive, bronchoscopy may be necessary. Successful repair and preservation of pulmonary function depends on early diagnosis.

Vascular Compression

Vascular compression of the trachea or main stem bronchus can result from incomplete regression of the embryonic branchial arch arteries during fetal development. The most common anomaly is a vascular “ring” consisting of a double aortic arch in which the vessel completely encircles the trachea and esophagus. Other variants include an ectopic aortic arch (passing behind the esophagus) or an aberrant origin of the right brachiocephalic artery.

Vascular rings cause inspiratory stridor and expiratory wheezing, neither of which change appreciably with the infant's position. Intermittent worsening of signs is sometimes seen during feeding as milk passing through the esophagus, further compressing the trachea. Additionally, feeding difficulty may occur because of esophageal compression.

When a previously undiagnosed infant first presents with these upper airway signs, she or he may be misdiagnosed as having tracheomalacia, bronchomalacia, or tracheobronchomalacia, until further imaging confirms the vascular abnormality.

The presence of an abnormally shaped mediastinum on a chest film often provides a clue to diagnosis. Endoscopy may identify tracheal or esophageal compression. An echocardiogram may define the vascular anomaly. Occasionally, cardiac

catheterization may be indicated. Decisions regarding surgical correction of this defect depend on the relative compromise of the trachea and esophagus. As a caution, the degree of compression may worsen as the infant grows.

Phrenic Nerve Paralysis

Stretch injury to the cervical nerve roots C3 to C5 during delivery can lead to temporary paralysis of the hemidiaphragm, and avulsion of the nerve roots can lead to permanent injury without intervention. Phrenic nerve paralysis occurs more commonly on the right. Brachial plexus injury or Horner syndrome is present in 70% to 80% of cases, and clavicular fracture is common. Infants who are at highest risk are those with birth weights greater than 4 kg, shoulder dystocia, or difficult breech presentations. Diminished ventilation is present on the affected side and the infant may be tachypneic or even be cyanotic if severely compromised. The chest radiograph will show varying degrees of atelectasis, a raised hemidiaphragm on the affected side, and the heart and mediastinum shifted toward the contralateral side. Fluoroscopy will demonstrate that the paralyzed diaphragm elevates during inspiration and descends on expiration *(paradoxical movement)*. Treatment is supportive in most cases because function usually will spontaneously return in several weeks. When there is nerve avulsion or permanent dysfunction, surgical plication may be necessary.

Eventration of the Diaphragm

The diaphragm consists of three layers: a muscular layer sandwiched between the pleural and peritoneal layers. Eventration of the diaphragm occurs when all or part of the diaphragmatic muscle is replaced by fibroelastic tissue. It is a rare disorder that results in a nonfunctioning diaphragm having highly elastic fibrous tissue. Partial defects are more common and usually occur on the right side. However, complete defects are more common on the left side and often are associated with other organ anomalies. Normal abdominal pressure permits the viscera easily to push the affected diaphragm upward into the hemithorax. In utero, this phenomenon may lead to pulmonary hypoplasia (although this is usually mild) whereas, occurring after birth, eventration can cause respiratory compromise by affecting lung expansion. Radiographic and fluoroscopic findings are similar to those of a paralyzed diaphragm, but a history of birth trauma or associated injuries is usually absent. With large defects, the appearance of bowel in the thoracic cavity on a chest radiograph may be mistaken for a diaphragmatic hernia. However, close inspection should reveal the thin, overlying diaphragmatic pleura. Treatment is supportive; defects that remain symptomatic beyond the neonatal period may require plication.

Pleural Effusion

Collection of fluid within the pleural cavity, if excessive, can result in significant respiratory embarrassment. Pleural effusions in the neonate may result from inflammation, fluid transudation, or frank leakage from disrupted vessels (either vascular or lymphatic). Small pleural effusions normally are present during the first

hours of life as fetal lung liquid resorbs from the airspaces, but a large pleural effusion or persistence beyond the first day of life is abnormal. Large effusions can result in significant respiratory compromise. Although initial management is similar regardless of cause, successful long-term management depends on accurately identifying the source of the pleural effusion.

Congenital Anomalies of the Chest Wall

Thoracic cage abnormalities represent a group of uncommon but frequently overlooked causes of respiratory distress in the neonate. They may be structural or functional in nature. The structural abnormality may be limited to the sternum or it may involve the entire thoracic cage. Sternal deformities include pectus excavatum, which is a relatively common but usually benign condition, and complete separation of the sternum often accompanies ectopia cordis and usually is lethal. Generalized structural abnormalities invariably involve some degree of thoracic restriction and pulmonary hypoplasia. Many of these abnormalities are themselves lethal or are part of a more generalized lethal disorder. Some conditions, however, such as achondroplasia and Ellis-van Creveld syndrome, are compatible with normal life. Functional anomalies result from dysfunctional chest wall musculature. Like structural defects, they may be restricted to the thoracic cage but, more often, they are part of a systemic disorder, such as congenital muscular dystrophy, glycogen storage disease, or myasthenia gravis. Severe congenital kyphoscoliosis does not itself usually cause neonatal respiratory problems but it may augment mild respiratory illness from another cause.

Most infants with thoracic cage abnormalities are readily recognized in the immediate newborn period, although a relatively protuberant abdomen may distract the clinician from the primary problem. Infants with restrictive thoracic cages (either structural or functional) will have tachypnea and retractions. The radiograph shows a narrow, elongated thoracic cage with high clavicles and depressed hemidiaphragms. Treatment is supportive, and in the absence of severe pulmonary hypoplasia or an underlying lethal disorder, infants may do relatively well, despite requiring initial mechanical ventilation.

Persistent Pulmonary Hypertension of the Neonate

The organ of gas exchange for the fetus is the placenta, not the lung. Placental blood flow is high and pulmonary blood flow is minimal. To achieve intrauterine gas exchange, blood returning to the right side of the heart is directed to the systemic (and thereby placental) circulation. This blood flow path occurs via two fetal right-to-left shunts, namely the foramen ovale, which shunts blood from the right to left atrium, and the ductus arteriosus, which shunts blood from the pulmonary artery to the descending aorta. Due to these shunts, less than 10% of the combined fetal ventricular output goes to the lungs.

At birth, dramatic lung changes must occur for the fetus to undergo a successful transition from placental to pulmonary gas exchange. Liquid is removed from the potential airspaces (see “Retained Fetal Lung Liquid Syndrome,” presented earlier), and blood flow course is redirected. After inflation of the lungs with air and a dramatic increase in oxygen tension within the lungs, a marked increase in cyclic

nucleotides occurs within pulmonary vascular smooth muscle, leading to vasodilatation. The resultant drop in pulmonary vascular resistance leads to a 10-fold increase in pulmonary blood flow, which causes left atrial pressure to exceed right atrial pressure, allowing the one-way flap across the foramen ovale to close. Flow across the ductus arteriosus reverses and, combined with increased blood oxygen tension, leads to gradual ductal closure over the first few hours of life.

In the syndrome of persistent pulmonary hypertension of the newborn (PPHN), this transition of the pulmonary circulation fails to occur normally (see section 3 of Chapter 56, Diseases of Pulmonary Circulation). Pulmonary vascular resistance and pulmonary arterial pressure remain high and blood flow continues largely to bypass the lungs as in fetal life. (This is why the term *persistent fetal circulation* has been used, although in a strict sense it is inaccurate because there is no longer a placental/umbilical circulation.) PPHN should be suspected if the degree of hypoxemia is out of proportion to pulmonary disease. PPHN is associated with many neonatal disorders, including RDS, meconium aspiration, air leak syndromes, perinatal asphyxia, congenital sepsis, and structural lung disorders such as pulmonary hypoplasia or alveolar-capillary dysplasia. PPHN can also be idiopathic. Infants with PPHN may be affected moderately or severely, depending on the extent of shunting. PPHN can be a self-limited disease, running a course over several days. In more severe cases, severe hypoxemia can lead to significant morbidity and mortality.

PPHN mortality previously has been as high as 50% to 60% but has improved significantly since the introduction of new treatment modalities including HFV, inhaled nitric oxide, and ECMO. Because nitric oxide increases cyclic guanosine monophosphate levels, selective phosphodiesterase inhibitors such as sildenafil are sometimes utilized in infants who have a prolonged course of PPHN or in whom pulmonary arterial hypertension develops after the newborn period, either idiopathic or as a result of underlying cardiorespiratory disease. The long-term benefits and risks of sildenafil are unknown.

Hyperviscosity Syndrome

Neonates with polycythemia (ie, a central hematocrit greater than 65%) are at risk for abnormally high blood viscosity, which interferes with regional tissue perfusion. Polycythemia may occur in several situations, including twin-twin transfusion, maternal-fetal transfusion, prolonged delayed cord clamping, home delivery, maternal diabetes, small-for-gestational-age infants, postmature infants, and infants with Down syndrome or Beckwith-Wiedemann syndrome. Signs generally relate to the degree of hyperviscosity and range from tachypnea to apnea, listlessness to irritability, hypoglycemia, and jitteriness to seizures.

Hyperviscosity syndrome presents during the first hours of life. The presentation may mimic congenital pneumonia, meconium aspiration, persistent pulmonary hypertension, or congenital heart disease. Affected infants are at risk for thrombotic injury unless the condition is reversed by partial blood volume exchange.

Congenital Heart Disease

In the neonate, significant congenital heart disease (CHD) typically presents as

cyanosis with minimal or no respiratory distress or cardiorespiratory failure. Congenital heart disease in which pulmonary blood flow is either excessive or nonrestrictive often presents with respiratory distress.

Infants who have right ventricular outflow tract obstructive lesions, such as D-transposition of the great arteries with an intact ventricular septum or tetralogy of Fallot, may be visibly cyanotic but appear to be comfortable. Cyanotic heart disease should be suspected in these infants, even if a murmur is absent, particularly if the infant has persistent low oxygen saturation or is hypoxemic in 100% oxygen. Conditions with left ventricular outflow tract obstruction or a large ventricular septal defect (VSD) may present without cyanosis but have pallor, systemic hypotension, marked respiratory distress, and often a loud murmur. Chest radiographs may show cardiomegaly or pulmonary vascular congestion. Simple left-to-right shunt lesions including small VSD, atrial septal defect, atrioventricular septal defect, and PDA do not often present with severe pulmonary edema or distress during the neonatal period because a relatively high pulmonary vascular resistance can restrict pulmonary blood flow. In contrast, PDA in preterm infants can present with pulmonary edema and respiratory distress. In the mixed types of CHD, there is an overlap in presentation and infants may be cyanotic as well as display signs of respiratory conditions such as tachypnea and retractions. This type of presentation, common with hypoplastic left heart syndrome and obstructed total anomalous pulmonary venous return (TAPVR), may initially be confused with sepsis, pneumonia, meconium aspiration, or even RDS. TAPVR deserves particular mention because it is not detected in utero and sometimes may be missed postnatally, even on repeated echocardiograms.

In fact, TAPVR with pulmonary venous obstruction is a surgically correctable congenital heart lesion for which neonates may mistakenly be placed on ECMO. A high index of diagnostic suspicion is warranted in a term or near-term infant who has a clinical and radiographic picture similar to surfactant-deficient respiratory distress or group B streptococcal sepsis.

Metabolic Disorders

Several hundred human inborn errors of metabolism (IEM) have been identified. These are a heterogeneous group, have variable presentations, and are relatively rare. Consequently, the possibility of an IEM may be overlooked. Even in an era of expanded newborn screening in many US states and in several other countries, newborn screening results may be initially unavailable or require special expertise for interpretation. An infant with an IEM that causes metabolic acidosis or metabolic encephalopathy may have deep and labored respirations (Kussmaul breathing). In many cases, the condition will rapidly progress to respiratory failure and apnea. Other manifestations of IEM result either from accumulation of a toxic product or deficiency of an essential substrate. In many IEMs, there may not be dysmorphic features, seizures, or vomiting. Instead, a there may be a pattern of worsening but nonspecific signs of multiple organ dysfunction that may not respond to routine intervention. It is important to maintain a high index of suspicion for IEMs, especially when there are no identified risk factors for respiratory distress. A delay in diagnosis and treatment can be catastrophic.

Intestinal or Renal Bicarbonate Wasting

Low plasma bicarbonate represents a metabolic acidosis that may present as tachypnea and respiratory distress in the neonate, although it usually does not occur in isolation. Of note, metabolic acidosis with a normal anion gap may be a feature of neonatal diabetes or may indicate bicarbonate loss via the kidneys or intestines. Gastroenteritis, renal tubular acidosis, and mineralocorticoid insufficiency are common causes. Differentiating the source of the acidosis is important because bicarbonate therapy may be harmful depending on the underlying problem.

CHAPTER 55

Pneumonitis and Interstitial Disease

Daiva Parakininkas

PEARLS

- Most pediatric pulmonary parenchymal disease occurs as the result of an infectious agent.
- Clinical evaluation for parenchymal lung disease in the pediatric patient should include a search for symptoms and signs associated with pulmonary disease, such as difficulty with feeding, exercise intolerance, chest pain, cough, tachypnea, dyspnea, cyanosis, orthopnea, clubbing of the nail beds, weight loss, and lethargy.
- Factors predisposing a child to bacterial pneumonia include having numerous siblings, having parents who smoke, preterm delivery, living in an urban environment, poor socioeconomic status, presence of an airway foreign body, impaired immune response, congenital and anatomic lung defects, abnormalities of the tracheobronchial tree, cystic fibrosis, and congestive heart failure.
- Viral agents are the leading cause of lower respiratory tract infection in infants and children.
- Three major clinical syndromes are associated with lower respiratory tract viral illnesses: (1) bronchitis, (2) bronchiolitis, and (3) pneumonia.
- Fungal infections are important in the differential diagnosis of pulmonary infections, particularly in children whose immunity is compromised and in healthy children who are exposed to pathogens in a particular geographic or environmental setting.
- Three forms of disease patterns in pneumocystosis are (1) childhood/adult, (2) infantile, and (3) chronic fibrosing observed in some patients infected with the human immunodeficiency virus.
- Chemical pneumonitis and/or pneumonia may be acquired by (1) aspiration, (2) inhalation, (3) ingestion, or (4) injection.
- Pulmonary hemorrhage is a potentially life-threatening event that can occur at any age. Clinical presentation varies from massive fatal hemoptysis to silent bleeding with respiratory distress and anemia.

Pneumonitis, or inflammation of the lung parenchyma, is perhaps the most common cause of life-threatening lower respiratory tract disease in pediatric patients. Although pneumonitis may result from noninfectious processes (Box 55.1), most pediatric pulmonary parenchymal disease occurs as the result of an infectious agent. Pneumonitis may involve the pleura, interstitium, and airways; pneumonia by definition must include alveolar consolidation. Whereas early parenchymal lung injury is associated with increased cellularity with minimal fibrosis, advanced disease is characterized by extensive fibrosis and destruction of gas exchange units. Physiologic changes may include the following: low lung volumes, diminished lung compliance, impaired gas exchange, and airflow limitation. This chapter addresses the principal potential causes of pediatric pulmonary parenchymal disease, including alveolar and interstitial disorders.

Box 55.1

Etiology of Pediatric Interstitial Lung Disease

Infectious

- Bacteria
- Virus
- Mycoplasma
- Chlamydia
- Rickettsia
- Protozoa
- Fungus

Noninfectious

- Acute lung injury
- Chemical agents
- Physical agents
- Radiation
- Drugs
- Congenital lymphangiectasia
- Metabolic disorders
- Bronchopulmonary dysplasia

- Hypersensitivity pneumonitis
- Cardiovascular causes
- Collagen/vascular disorders
- Mixed connective tissue disorders
- Idiopathic pulmonary fibrosis
- Pulmonary hemorrhage syndromes
- Pulmonary hemosiderosis
- Pulmonary venoocclusive disease
- Desquamative interstitial pneumonia
- Lymphocytic infiltrative disorders
- Lymphocytic interstitial pneumonitis
- Familial erythrophagocytic lymphohistiocytosis
- Angioimmunoblastic lymphadenopathy
- Sarcoidosis
- Inherited diseases
- Malignancy
- Leukemia
- Hodgkin disease
- Non-Hodgkin lymphoma
- Histiocytosis X

Pathogenesis

Regardless of the cause, pneumonitis often follows a common pathogenesis. The initial parenchymal injury can result from mechanisms that directly damage the endothelium or epithelial cells. Other agents may injure the lung indirectly by one or more of the following processes:

1. Generation of toxic radicals

2. Recruitment of inflammatory cells (eg, neutrophils)

3. Activation of complement and/or release of chemotactic factors

If these processes go unchecked, alterations may occur in the lung parenchyma and connective tissues leading to end-stage fibrosis. This condition is characterized by severe destruction of gas exchange units and airways and the development of parenchymal cystic lesions.

Pathophysiology

Changes in lung volumes in pulmonary parenchymal disease depend primarily on the intensity of the alveolitis and stage of the disease process. Acute severe pneumonitis with intense alveolitis is characterized by moderate to severe reduction in both vital capacity (VC) and total lung capacity. It is also associated with a reduction in pulmonary compliance. In the early stages, patients with chronic interstitial diseases involving the lung parenchyma often have normal VC and total lung capacity. Subsequent reduction in lung volumes and pulmonary compliance occurs as the disease progresses and pulmonary fibrosis ensues.[1] Expiratory flow rates are usually preserved in persons with pneumonitis involving the lung parenchyma, and major obstructive defects, although reported, are rare. The carbon monoxide diffusing capacity, one of the earliest and most sensitive tests of parenchymal inflammation, is diminished in persons with interstitial lung disease (ILD). A reduction in the carbon monoxide diffusing capacity is not specific and may be found with other parenchymal disorders. Early in the course of parenchymal disease, resting arterial oxygen tension may be normal, but there is often mild alveolar hyperventilation with reduction in alveolar carbon dioxide tension and widening of the alveolar-arterial oxygen gradients ($P_{AO_2} - Pa_{O_2}$). With exercise, hypoxemia and an increased $P_{AO_2} - Pa_{O_2}$ become exaggerated because of ventilation/perfusion (V/Q) imbalance. V/Q mismatch is attributed to regional alterations of flow, altered parenchymal compliance, and increased obstruction to pulmonary airflow. Progressive alveolitis and subsequent derangement of gas exchange lead to deterioration of ventilatory efficiency and markedly increased work of breathing. Adequate oxygenation may become impossible even with the use of high-flow supplemental oxygen. Resting hypercapnia, pulmonary hypertension, and eventual right ventricular dysfunction with heart failure are common sequelae.[2-4]

Diagnosis

Diagnosing parenchymal lung disease in the pediatric patient may be quite challenging because of extreme variability in the presentation of disease. Clinical evaluation of the child should include a search for symptoms and signs associated with pulmonary disease, such as difficulty with feeding, exercise intolerance, chest pain, cough, tachypnea, dyspnea, cyanosis, orthopnea, clubbing of the nail beds, weight loss, and lethargy. In the child with diffuse alveolar disease, auscultative findings may be normal unless significant consolidation or small airway involvement is present. Fine crackles that may be heard throughout the chest late in inspiration are a characteristic finding of small airway disease. These rales are

produced by the opening of occluded small peripheral airways.

Laboratory Diagnosis

The chest radiograph is critical in the diagnosis and management of pulmonary parenchymal disease. In children with ILD the classic radiographic features that are present in adults may be absent. Computed tomography scanning,[5-7] gallium lung scanning, and bronchoalveolar lavage (BAL)[8-10] are useful techniques in the diagnosis and management of diseases involving the lung parenchyma. Pulmonary function testing is important and usually can be performed reliably in children who are older than 4 years.[1,11]

Bacterial Pneumonitis

Bacterial infections of the lower respiratory tract continue to account for a significant number of hospital admissions. The frequency of bacteria as etiologic agents of lower respiratory tract infection varies from 10% to 50%, depending on the study population and the methods of evaluation used.[12,13] In a large study of pediatric patients with lower respiratory tract infection, an etiologic agent was identified in nearly 50% of the patients. Bacteria accounted for 10% to 15% of the causative agents identified.

Factors predisposing to bacterial pneumonia include having numerous siblings, having parents who smoke, preterm delivery, living in an urban environment, and poor socioeconomic status. Hospitalization also increases the risk of contracting bacterial pneumonia because of the clustering of ill patients in confined areas, administration of immunosuppressive therapy, and various medical and surgical interventions that enhance the opportunity for colonization and infection. Additional factors that increase susceptibility to bacterial pneumonia include the presence of an airway foreign body,[14] impaired immune response,[15-19] congenital and anatomic lung defects, abnormalities of the tracheobronchial tree, cystic fibrosis,[20] and congestive heart failure.

Definition

Bacterial pneumonia is an inflammatory process of the lungs that may involve interstitial tissue and pleura in its evolution but always progresses to alveolar consolidation.

Pathophysiology

Pneumonia occurs when pulmonary defense mechanisms are disrupted and bacteria invade the respiratory system by aspiration or hematogenous spread. In most instances pneumonia appears to be a consequence of aspiration of a high inoculum of pathogenic bacteria. Viruses are often responsible for enhancing the susceptibility of the respiratory tract to bacterial infection. Less frequently, bacterial pneumonia may be the result of defects in host immunity because of young age, underlying immune dysfunction, or immunosuppressive therapy. Pneumonia may also occur when host defenses are mechanically disrupted because of tracheostomy or

endotracheal intubation. The presence of respiratory pathogens in the terminal bronchioles and alveoli induces an outpouring of edema fluid and large numbers of leukocytes into the alveoli.[2,21] Macrophages subsequently remove cellular and bacterial debris. The infectious process may extend further within the lung segment or disseminate through infected bronchial fluid to other areas of the lung. The pulmonary lymphatic system enables bacteria to reach the bloodstream or visceral pleura.

With consolidation of lung tissue, VC and lung compliance markedly decrease and intrapulmonary right-to-left shunt and V/Q mismatch occur, resulting in hypoxia. Subsequently, pulmonary hypertension may occur because of significant oxygen desaturation and hypercapnia, often leading to cardiac overload.

Clinical Features

Signs and symptoms of bacterial pneumonia vary with the individual pathogen, the age and immunologic condition of the patient, and the severity of the illness. Clinical manifestations, especially in newborns and infants, may be absent. General or nonspecific complaints include fever, chills, headache, irritability, and restlessness. Individual patients may have gastrointestinal complaints including nausea, vomiting, diarrhea, abdominal distention, or pain. Specific pulmonary signs include nasal flaring, retractions, tachypnea, dyspnea, and occasionally apnea.

Tachypnea is the most sensitive index of disease severity. The sleeping respiratory rate is often a valuable guide to diagnosis. On auscultation, diminished breath sounds are frequently noted. Fine crackles that may be heard in children and older patients are commonly absent in infants. Because of the relatively small size of the child's thorax and the thin chest wall, broad transmission of the breath sounds occurs and the classic findings of consolidation are often obscured. Pleural inflammation may be accompanied by chest pain at the site of inflammation. This pleuritic pain may cause “splinting,” which restricts chest wall movement during inspiration and reduces lung volume.

Extrapulmonary infections that may be present in some children include abscesses of the skin or soft tissue *(Staphylococcus aureus);* conjunctivitis, sinusitis, otitis media, and meningitis (*Streptococcus pneumoniae* or *Haemophilus influenzae*); and epiglottitis *(H. influenzae).*

Radiographic Features

Bacterial pneumonia is typically characterized by defined areas of consolidation with either segmental or lobar involvement. Lobar consolidation is the most characteristic, but multilobed disease is not unusual. The findings of pleural effusion, pneumatocele, or abscess are also strongly indicative of a bacterial infection. Staphylococcal pneumonia is suggested by rapid clinical and radiographic progression of disease, particularly in a young infant. Evidence of an abscess or pneumatocele further suggests a diagnosis of staphylococcal or gram-negative pneumonia such as *Klebsiella.* Group A streptococcal pneumonia may initially present with a diffuse interstitial pattern before the development of consolidation. Except for *Pseudomonas,* which may have a diffuse nodular appearance in the lower lobes, pneumonias caused by gram-negative organisms have no specific

radiographic pattern. Anaerobic pulmonary infection is also associated with lung abscesses or air fluid levels.

Diagnosis

Bacterial pneumonia is suggested by fever, leukocytosis (>15,000 white blood cells), and increased band forms on the peripheral blood smear. Examination of the sputum may be helpful in establishing the diagnosis of bacterial pneumonia; however, it is often difficult to obtain a satisfactory sputum sample in pediatric patients unless transtracheal aspiration or bronchoscopy is used. Transtracheal aspiration, although useful in adolescents and adults, is associated with significant complications in infants and young children. If a sputum sample is obtained (an adequate specimen must have >25 polymorphonuclear cells and <25 epithelial cells per high-power field), the Gram stain should be examined for a predominant bacterial pathogen and cultures should be performed with the appropriate antibiotic susceptibility studies. Counterimmune electrophoresis (CIE) performed on sputum specimens has proved helpful in establishing the diagnosis in both adults and children. Bacterial pneumonia is accompanied by bacteremia in a significant number of cases; hence blood cultures should be obtained before initiation of antibiotic therapy. Circulating antigens in *S. pneumoniae* and *H. influenzae* may be detected in the blood with CIE,[22] polymerase chain reaction (PCR),[23-25] or latex agglutination.[26,27]

If a significant pleural effusion is present, a diagnostic thoracentesis should be performed for the purposes of Gram stain and culture. Culturing pleural fluid has a relatively high yield in patients who have not received previous antibiotic therapy. If the Gram stain of pleural fluid is negative, CIE or latex agglutination should be performed because bacterial antigen may be detected in the fluid even after the initiation of antibiotics.

BAL should be considered in the management of a severely ill child in order to make a prompt diagnosis.[9,10] Making a prompt diagnosis is essential for the patient with progressive disease who has responded poorly to initial therapy or for the child with underlying immunodeficiency for whom empiric antibiotic treatment may be hazardous. In such instances, if the BAL is nondiagnostic, then lung aspiration or biopsy should be considered.[28] Material may be obtained through closed-needle biopsy, percutaneous needle aspiration, or an open lung biopsy. Positive results for such procedures in carefully selected cases identify an etiologic agent in 30% to 75% of cases, with open lung biopsy having the highest yield.[18,29]

Specific Pathogens

Group B Streptococci

Group B streptococci can cause infection in people of any age; however, these organisms are common pathogens in infants younger than 3 months.[30] Early-onset illness is often associated with maternal fever at the time of delivery, prolonged rupture of membranes, amnionitis, prematurity, and low birth weight.

Infected neonates usually manifest clinical symptoms within the first 6 to 12 hours of life. Symptoms include fever, respiratory distress, apnea, tachypnea, and hypoxemia. By 12 to 24 hours of age, signs of cardiovascular collapse are often apparent. Frequently, the syndrome of pulmonary hypertension of the newborn is

present, and pulmonary or intracranial hemorrhage may become the terminal event.

Isolation of the organism establishes the diagnosis. Cultures from blood and cerebrospinal fluids must be obtained in all instances of suspected group B streptococcal pneumonia. Rapid diagnostic techniques have been helpful in providing early diagnoses. The radiographic findings in neonates with group B streptococcal pneumonia can be either a lobar (40%) or a diffuse reticulonodular pattern with bronchograms similar to findings of respiratory distress syndrome.

Aggressive cardiovascular and ventilatory support is usually required, particularly in the early stages of the disease. Antibiotic therapy should include a combination of ampicillin or penicillin and an aminoglycoside agent.

Although in the past the mortality rate of patients with group B streptococcal pneumonia could be as high as 50% to 60%, recent studies suggest improvement with prompt initiation of therapy and even better outcomes with maternal prophylaxis.[31] Some infants experience a second episode of infection 1 to 2 weeks after discontinuation of antibiotic therapy. Infants with group B streptococcal pneumonia and meningeal involvement (30%) may demonstrate significant neurologic deficits (20%-50%).

Streptococcus pneumoniae

S. pneumoniae is a gram-positive diplococcus with at least 84 sera types; however, 80% of the serious infections are caused by only 12 sera types. Streptococci are a major cause of pneumonia in the United States. Victims are usually infants younger than 2 years, with a peak age between 3 and 5 months. Patients with asplenia, functional hyposplenia, or malignancy or those receiving immunosuppressive drugs are at special risk of the development of invasive disease.[32]

The radiographic finding in infants is often a patchy bronchopneumonia. Lobar consolidation is not uncommon. Penicillin is the drug of choice in the treatment of persons with streptococcal pneumonia. However, organisms relatively resistant to penicillin occur in 3% to 40% of culture-positive patients recorded in studies from different parts of the United States.[33] In such instances, pneumonias have been effectively treated with vancomycin or high-dose β-lactam cephalosporin agents such as cefuroxime, ceftriaxone, or cefotaxime. Disease resulting from penicillin-resistant pneumococci should be considered in patients who received therapy with β-lactam antibiotics.[33-35]

The pneumococcal 13-valent conjugate vaccine is recommended for all children aged 5 and younger. It is also recommended for certain children aged 60 to 71 months with chronic medical conditions, immunosuppressive conditions, functional or anatomic asplenia, cerebrospinal fluid leaks, or cochlear implants. The pneumococcal polysaccharide vaccine, a 23-valent formulation, is recommended in children 2 years and older with an increased risk of invasive pneumococcal disease.[36]

Haemophilus influenzae

Haemophilus organisms are small, nonmotile, gram-negative rods that occur in both encapsulated and nonencapsulated forms. Approximately 90% to 95% of invasive disease is caused by the encapsulated sera type B. A pleural effusion or empyema is detected in nearly 40% of patients with *H. influenzae* pneumonia. There is an extremely high incidence of bacteremia in this disease. Serious complications such as

epiglottitis, meningitis, and pericarditis can be diagnosed in 15% to 20% of patients. Cellulitis, anemia, and septic arthritis occur infrequently.

In a hospitalized patient, administration of the combination of ampicillin and chloramphenicol or a single cephalosporin such as cefuroxime, cefotaxime, or ceftriaxone generally is effective therapy.[33,37] The mortality rate in appropriately treated patients is generally considered less than 5% and often is related to associated meningitis, epiglottitis, or pericarditis rather than the pneumonic process itself. Hib conjugate vaccine is an important measure in reducing the incidence of *Haemophilus*-related disease and should be administered to all children.[33,38,39]

Staphylococcal Pneumonia

Primary *S. aureus* pneumonia has decreased in frequency in recent years but still accounts for approximately 25% of cases in young infants. The incidence of secondary or metastatic dissemination has increased since 1972. Patients with primary pneumonia present with fever and respiratory symptoms, whereas those with metastatic disease often present with fever, generalized toxicity, and musculoskeletal symptoms. In patients presenting with primary staphylococcal pneumonia, the disease is often preceded by an upper respiratory tract infection.[40,41] Pleural effusion or empyema develops in nearly 80% of the patients with primary staphylococcal pneumonia and is extremely common in patients with metastatic disease. It is not unusual for patients with staphylococcal pneumonia to remain bacteremic long after the initiation of appropriate antibiotic therapy.

Radiographic findings of *S. aureus* pneumonia differ according to the stage of disease. They vary from minimal changes to consolidation (most common) and are associated with pleural effusion (50% to 60%) or pneumothorax (21%). Pneumatoceles usually appear during the convalescent stage and may persist for prolonged periods in asymptomatic patients. Antibiotic therapy should be administered intravenously and include a drug that is resistant to inactivation. Strong consideration should be given to providing antibiotic coverage for methicillin-resistant *S. aureus,* which can account for 1% to 30% of isolates, depending on the prevalence in the area.[40] The duration of therapy is usually lengthier in patients with staphylococcal disease than for patients with other bacterial pneumonias and consists of 21 days or more of treatment. The mortality rate of staphylococcal pneumonia varies from 23% to 33%. An increased incidence of mortality is usually associated with younger age, inappropriate initial antimicrobial therapy, or failure to drain an empyema appropriately.

Mycoplasma Pneumonia

Mycoplasma organisms are the smallest free-living microorganisms. They lack a cell wall and are pleomorphic. Mycoplasma is an uncommon cause of pneumonia in children younger than 5 years but is the leading cause of pneumonia in school-aged children and young adults. Illness can range from a mild upper respiratory tract infection to tracheobronchitis to pneumonia. Symptoms include malaise, low-grade fevers, and headache. In 10% of children a rash develops that usually is maculopapular. Cough, if it develops, usually occurs within a few days and may continue for 3 to 4 weeks. Initially the cough is nonproductive but then may become productive and is usually associated with widespread rales on physical examination.

Roentgenographic abnormalities vary but are usually bilateral and diffuse.[33]

Isolation of *Mycoplasma* by culture is complicated by the requirement for special enriched broth or agar media, which are not widely available; it is successful in only 40% to 90% of cases and requires 7 to 21 days. A fourfold increase in antibody titer between acute and convalescent sera is diagnostic, but the time involved is lengthy, providing only a retrospective diagnosis. Complement fixation and immunofluorescent and several enzyme immunoassay antibody tests have been developed but are of limited diagnostic value.[33] Serum cold agglutinins with titers of 1 : 32 or greater are present in more than 50% of patients with pneumonia by the beginning of the second week of illness. PCR test has become an important means of diagnosing *M. pneumoniae* infections in clinical practice and allows for institution of therapy directed at the causative pathogen.[41] Treatment of upper respiratory tract infections or acute bronchitis is rarely indicated, but treatment with erythromycin or another macrolide such as azithromycin is indicated for persons with pneumonia or otitis media.

Gram-Negative Bacteria

Pneumonia caused by gram-negative enteric bacteria, especially *Pseudomonas,* is almost always found in patients with underlying pulmonary disease, compromised immune status, or those receiving prolonged respiratory therapy.[42,43] Gram-negative enteric bacteria are a frequent cause of nosocomial infection in critical care units. These organisms can produce a severe necrotizing pneumonia that is associated with an increase in morbidity.[44]

Legionella pneumophila

Pneumonia that occurs as a result of *Legionella pneumophila* has been reported infrequently in the pediatric age group.[45-48] The onset of this disease is characterized by high, unremitting fever; chills; and a nonproductive cough.[46] Extrapulmonary manifestations include gastrointestinal symptoms such as diarrhea, liver involvement, and confusion. Chest radiographs typically consist of peripheral nodular infiltrates and pleural effusions. Cavitation occurs only in immunosuppressed individuals. Death in the normal host is unusual if prompt therapy with azithromycin or erythromycin is initiated.

Anaerobic Bacteria

Pneumonia resulting from anaerobic upper respiratory flora is uncommon in healthy children. When it does occur, it is frequently associated with risk factors such as underlying pulmonary disease, a CNS disorder (including seizures), a postanesthetic state, and aspiration of a foreign body. Lung abscess and empyema are frequent complications in persons with anaerobic bacterial pneumonias.

Complications

The mortality rate in persons with uncomplicated bacterial pneumonia is less than 1%. Death is more common in children with complicated disease or an underlying disorder. The most frequent complications of bacterial pneumonia are pleural effusion and empyema (Table 55.1). Thoracentesis should always be performed if

fluid is present to facilitate an etiologic diagnosis and establish the character of the fluid. Tube thoracostomy is indicated if a large amount of fluid is present and is producing respiratory compromise or if purulent fluid is obtained by thoracentesis. Empyema may extend locally to involve the pericardium, mediastinum, or chest wall. Evidence of empyema extension should be considered in the child who is unresponsive to antibiotic therapy.[28]

TABLE 55.1

Major Sequelae/Life-Threatening Complications Associated With Bacterial Infections

Complication/Sequelae	Organism
Necrotizing pneumonia	Anaerobic, GNB
Respiratory failure	GBS
Shock	GBS, SP, H. flu, GNB
Apnea	GBS
Pneumothorax	H. flu
Pneumatoceles	H. flu, anaerobic, staph, SP, GAS
Abscess (lung)	Staph, SP, anaerobic
Pleural effusion	H. flu, GAS, SP, staph
Empyema	H. flu, staph, SP
Epiglottitis	H. flu, GAS
Meningitis	H. flu, GBS, SP
Encephalopathy	Legionella
Pericarditis	H. flu
Bone/joint	H. flu, staph
Kidneys	Staph

GAS, Group A streptococcus; GBS, group B streptococcus; GNB, gram-negative bacteria; *H. flu, Haemophilus influenzae; SP, Streptococcus pneumoniae; Staph, Staphylococcus aureus.*

When tube thoracostomy/surgical drainage is required, it should be discontinued as soon as drainage has substantially decreased. For patients with staphylococcal empyema, streptococcal pneumonia, or *H. influenzae* empyema, 3 to 7 days of drainage is usually sufficient. Patients with empyema require prolonged antimicrobial therapy and careful follow-up.

Pneumothorax and pneumatoceles can be seen with almost any bacterial pneumonia but are especially common with staphylococcal disease.[49] Such pneumatoceles require no special therapy and usually resolve. Lung abscess is an infrequent complication of *H. influenzae* and pneumococcal pneumonia and is most often encountered with staphylococcal disease or anaerobic bacteria.

Prognosis is usually excellent even in persons with severe bacterial pneumonia complicated by empyema. Long-term follow-up of children with empyema has demonstrated remarkably few, if any, residual pulmonary function abnormalities and remarkable clearing of chest roentgenograms. In contrast to adults with empyema, children seldom require surgical procedures such as decortication. However, follow-up chest radiographs should be obtained on all patients with bacterial pneumonia to document complete resolution. Such radiographic follow-up studies are probably not indicated until at least 6 to 8 weeks following the initiation of antibiotic therapy.

Therapy

Therapy for persons with bacterial pneumonia should include appropriate IV

antibiotic treatment directed toward the specific pathogen, if it is known (Table 55.2). Localized or compartmental complications such as empyema, lung abscess, pericarditis, or septic joints require appropriate surgical drainage and antibiotic therapy. Prevention via immunization or chemoprophylaxis has changed the incidence and epidemiology of pneumonitides significantly. Options for immunization, active or passive, and chemoprophylaxis for various etiologic agents are listed in Table 55.3.

TABLE 55.2

Bacterial Pneumonia Therapy

Disease/Organism	Therapy
Undetermined Organisms	
Serious, life-threatening pneumonia, nonsuppressed host	Cefotaxime or ceftriaxone + azithromycin + vancomycin
	Bronchial lavage or needle aspiration of lung may be necessary to establish diagnosis
Suppressed neutropenic host	Imipenem/meropenem *or* piperacillin or ceftazidime + aminoglycoside ± clindamycin
	Vancomycin not included in initial therapy unless high suspicion or if patient has indwelling line. Ampho not used unless still febrile after 3 days/high suspicion. Bronchial lavage, needle/open biopsy may be necessary to establish diagnosis
Lung abscess	Clindamycin *or* ticarcillin/clavulanate *or* piperacillin/tazobactam
Specific Organisms	
Pneumonia With Empyema	
Streptococcus pneumoniae, group A strep	
Penicillin susceptible	Cefotaxime or ceftriaxone + chest tube drainage
Penicillin resistant	Vancomycin ± rifampin + chest tube drainage
Staphylococcus	
Methicillin sensitive	Nafcillin or oxacillin + chest tube drainage
Methicillin resistant	Vancomycin + chest tube drainage
Pneumonia Without Empyema	
Haemophilus influenzae	Ampicillin or cefotaxime or ceftriaxone + chloramphenicol
Klebsiella pneumonia	Meropenem
Escherichia coli, Enterobacter	Aminoglycoside or cephalosporin
Legionella	Azithromycin or erythromycin ± rifampin
Pseudomonas	Aminoglycoside + anti-*Pseudomonas* penicillin or aminoglycoside + ceftazidime
Mycoplasma pneumoniae	Erythromycin or azithromycin or clarithromycin

TABLE 55.3

Preventive Measures

Organism	Immunization	Chemoprophylaxis
Cytomegalovirus	IVIG: prophylaxis in seronegative transplant recipients	Ganciclovir or valganciclovir
Haemophilus influenzae type b	Capsular polysaccharide vaccine *or* conjugate vaccine	Rifampin in the face of incomplete immunization and exposure
Influenza	Inactivated virus produced in chicken embryos	Oseltamivir (A or B) *or* amantadine/rimantadine (A)
Measles	Live virus vaccine *or* IVIG for immunocompromised patients	None
Streptococcus pneumonia	Purified capsular polysaccharide antigens of 23 pneumococcal serotypes vaccine *or* multivalent protein conjugate vaccine	Penicillin VK for functional or anatomic asplenia until age 5 yr
Pneumocystis carinii	None	Trimethoprim-sulfamethoxazole *or* pentamidine or dapsone or atovaquone

RSV	RSV-IVIG *or* palivizumab (monoclonal antibody)	None
Group B strep	None	Intrapartum antibiotics

IVIG, intravenous immunoglobulin; *RSV*, respiratory syncytial virus.

Viral Pneumonitis

Infection is the most common cause of pulmonary interstitial disease in children, and viral agents are the leading cause of lower respiratory tract infection in infants and children. The viral agents listed in Table 55.4 account for the greatest percentage of pediatric pulmonary disease. Nearly 85% of all hospitalizations of children younger than 15 years occur during outbreaks of respiratory syncytial, parainfluenza, or influenza virus.

TABLE 55.4

Viral Agents Associated With Pediatric Interstitial Lung Disease

Agent	Frequency
Respiratory syncytial virus	+++++
Parainfluenza virus	++++
Adenovirus	+++
Influenza virus	+++
Cytomegalovirus	+
Enterovirus	+
Rhinovirus	+
Measles	+

The diagnosis of viral pneumonia in children is frequently based on the clinical presentation, epidemiologic setting, and exclusion of bacterial pathogens by negative cultures. A specific agent is identified in only approximately 50% of cases of presumed viral pneumonia. Pediatric viral respiratory tract infections occur most commonly during the winter, with distinct peaks during midwinter and early spring in temperate climates. Closed population groups provide for greater spread of respiratory viruses and increased recognition of viral pneumonias.

Pathophysiology

The mechanism of infection for most respiratory viruses appears to be a progressive spread from the larger airways to the alveoli. The respiratory epithelial cell is the major target of cytopathic effect. The normal ciliated columnar epithelium may become markedly dysplastic with loss of the overlying cilia.[50,51] Areas of ulceration then occur as segments of the mucosal surface desquamate into the bronchial lumen. Impaired mucociliary clearance occurs, and altered stimulation of nerves mediating bronchial smooth muscle tone leads to increased airway resistance.[52] Enhanced mucus formation along with mucosal debris may lead to obstruction of the bronchioles, luminal narrowing, distal air trapping, and hyperinflation of various lung segments. In advanced disease with complete small airway obstruction, atelectasis results, causing hypoxemia as a result of intrapulmonary shunting and V/Q imbalance.

In persons with severe viral pneumonia, widespread parenchymal injury caused by a necrotizing alveolitis may occur. Alveolar round cell infiltrates occur often, with

subsequent hyaline membrane formation and intraalveolar hemorrhage, which produces extensive parenchymal destruction and diminished lung compliance, decreased lung volumes, and intrapulmonary shunting.[53]

Diagnosis

Although the clinical presentations of illness by respiratory viruses overlap, presumptive diagnosis of the specific etiology is based on clinical presentation, setting, and, most importantly, epidemiologic information. In the past, virus isolation or seroconversion was necessary for a definitive diagnosis. Today many respiratory viral infections can be diagnosed through the use of new techniques.[54]

Viral specimens should be obtained as early as possible during the period of greatest viral excretion. Cultures may be negative in up to 40% of patients during acute viral respiratory tract disease; failure to isolate a virus is not definitive evidence against the diagnosis of viral pneumonia. Serologic tests including complement fixation, hemagglutination inhibition, enzyme-linked solid-phase assays (enzyme-linked immunosorbent assays), and antibody assays have been used in the diagnosis of viral infection. Histologic evidence of infection in biopsy or postmortem specimens may be helpful, particularly when intranuclear inclusions are documented. Rapid diagnostic techniques focus on detection of the virus or its components in the sample. These new techniques include refinements in the use of immunofluorescence, enzyme immunoassay, time-resolved fluoroimmunoassay, latex agglutination assays, and use of nucleic acid hybridization methods, such as DNA probes and PCR.[55-58]

Three major clinical syndromes are associated with lower respiratory tract viral illness:

1. Bronchitis: Acute bronchitis is a febrile illness associated with a new productive cough. Symptoms of upper respiratory tract infection may be present. Acute bronchitis can adversely affect respiratory function, particularly in patients with chronic pulmonary impairment, leading to hospitalization of persons with marginal lung function.

2. Bronchiolitis: Symptoms result from airflow obstruction caused by localized inflammation of the terminal respiratory bronchioles. The development of cough; tachypnea with intercostal retractions; fine, moist, inspiratory crackles; and expiratory wheezes are characteristic. Hypoxemia and cyanosis are often present.[59]

3. Pneumonia: Primary viral pneumonia is frequently a mild illness characterized by a mild cough and one or more segmental infiltrates on chest radiograph. Although it is usually a self-limited process, in some persons the pneumonic process may progress with extensive parenchymal injury, diffuse interstitial alveolar infiltrates, and severe hypoxemia. Bacterial superinfection is heralded by increased temperature, change in sputum, and signs of localized consolidation several days after the initial onset of symptoms.

Radiographic Findings

Differentiation of bacteria from viral pneumonia cannot be made solely on the

radiographic appearance. Children with presumed viral pneumonia, however, may have several radiographic findings, including the following:

1. Peribronchial thickening and perihilar linear densities

2. Partial lobar or patchy involvement in multiple areas of the lung

3. Shifting regional infiltrates

4. Areas of hyperinflation and atelectasis

Hilar adenopathy is usually absent. Diffuse bilateral infiltrates similar to those reported in acute respiratory distress syndrome (ARDS) have been found in persons with severe influenza, adenovirus, and respiratory syncytial virus (RSV) pneumonias.[60] Pleural effusions can occur in both adenovirus and parainfluenza pneumonias. Pulmonary calcifications/nodules have been described in the convalescent phase of varicella and measles.

Specific Pathogens

We review the most common viral pathogens that cause pneumonitis in children but have elected to exclude such viruses as Hantavirus that are beyond the scope of this chapter. There continue to be viruses that are identified as pathogens in viral pneumonitis but as of yet do not have effective chemoprophylaxis or therapy such as the human metapneumovirus or the bocavirus, but their inclusion would not add to our discussion. Please refer to more up-to-date journal articles for specific pathogens of interest.[25,61]

Respiratory Syncytial Virus

RSV is the most common cause of bronchiolitis and pneumonia in the United States in children between the ages of 6 months and 3 years. The disease produced by RSV varies from upper respiratory tract infection to severe bronchiolitis and pneumonia with wheezing and respiratory failure.[59] Higher mortality rates and greater severity with prolonged symptoms occur in infants and children younger than 6 weeks of age and in those who have a history of prematurity, chronic lung disease, cardiopulmonary disease, congenital heart disease, pulmonary hypertension, or neuromuscular impairment, as well as in those receiving chemotherapy or immunosuppressive therapy.[16,62-69] Signs of RSV pneumonia include wheezing, dyspnea, pulmonary infiltrates, and areas of atelectasis and hyperinflation on the chest radiograph. RSV infection may result in increased airway reactivity and airway resistance that persists for months. Significant respiratory tract shedding of virus continues for up to 21 days from the onset of illness. Nosocomial spread of RSV infection is common, and early diagnosis and appropriate isolation techniques are critical in hospitalized patients.

Methods for diagnosis of RSV include viral isolation in cell culture, immunofluorescence of exfoliated nasopharyngeal epithelial cells for detection of RSV antigens, and enzyme immunoassay for detection of RSV antigens in nasal secretions.[70,71] PCR technology is available for diagnosis of RSV illness.

All hospitalized patients with bronchiolitis and RSV pneumonia should be

monitored for hypoxia, hypercarbia, and the need for ventilatory assistance. Supportive care includes the use of humidified oxygen, secretion clearance, and hydration.[72,73] Mechanical ventilation for respiratory failure is usually well tolerated. Extracorporeal membrane oxygenation has been used successfully in infants who do not respond to conventional ventilation.[74,75] The routine administration of bronchodilators and corticosteroids is not warranted; use should be individualized on the basis of clinical reponse.[75,76] Passive immunoprophylaxis has proved useful in high-risk populations in preventing RSV infection, as has palivizumab, a humanized mouse monoclonal antibody.[33,77-81] The incidence of bacterial superinfection in persons with RSV disease is low; therefore prophylactic antibiotics are not recommended for RSV disease.[62,82,83] It is not unusual for an infant with RSV to require hospitalization for 7 to 10 days following the onset of illness. Long-term complications of RSV infection may include persistent bronchial reactivity, with lower respiratory tract symptoms in more than 70% of infants in the year following hospitalization.[84] Whether moderately severe RSV infection predisposes a person to asthma later in life remains controversial.[85-89]

Parainfluenza Virus

Parainfluenza virus (types 1 and 2) is more often associated with laryngotracheobronchitis and croup than with pneumonia (usually type 3). Parainfluenza is second only to RSV as an etiology of lower respiratory tract disease responsible for the hospitalization of children.[90-96] The pneumonia associated with parainfluenza is typically mild; however, fatal cases with prolonged viral shedding have been reported in patients with severe combined immunodeficiency disease.[97-100] Conferred immunity following infection is low; repeat infection occurs in nearly 50% of patients by age 30 months, although they result in progressively milder illness. Parainfluenza virus, like RSV, has demonstrated ability to elicit an immunoglobulin IgE-specific antibody response.[93] Rapid identification of parainfluenza virus by either fluorescent or enzyme-linked immunologic techniques is possible, but results are variable depending on the viral type and antisera used. Viral culture may take up to a week. PCR methods are available for detection and differentiation, with high sensitivity and specificity. Treatment is supportive.

Adenovirus

Adenoviruses are responsible for approximately 3% of the pneumonias occurring in children. Clinical features are similar to other viral pneumonias except that the onset of illness is often gradual, occurring over several days. Of the 51 serotypes, types 3, 4, and 7 are the most common causes of lower respiratory tract disease in children. Adenovirus type 7 is most commonly associated with severe pneumonitis in infants and children and has a significant incidence of mortality and morbidity.[41,101-105] In 2007, a new strain of adenovirus 14 was isolated in previously healthy infants and young adults in the United States in whom fatal pneumonia developed.[106] A clinical presentation similar to that of bacterial pneumonia, with massive pleural effusion, rhabdomyolysis, and myoglobinuria, has been reported with adenovirus type 21.[107] In many infants with documented adenovirus respiratory tract infection, chronic pulmonary disease that manifests as persistent atelectasis, bronchiectasis, and recurrent pneumonitis with areas of hyperinflation and interstitial fibrosis develops.

Bronchiectasis and restrictive lung disease have been documented in children following acute adenovirus infection. Adenovirus pneumonia is the most common cause of bronchiolitis obliterans in children, and unilateral hyperlucent lung syndrome has been reported.[108-112] Disseminated adenovirus occurs and is usually associated with infection by serotype 3, 7, or 21. It occurs most frequently in infants younger than 18 months and usually involves the heart, pericardium, liver, pancreas, kidneys, CNS, and skin.[113] Fatal cases of adenovirus and pneumonia can occur in previously healthy young individuals. Diagnosis is made by cell culture and antigen and DNA detection by PCR. Adenovirus typing is available from some reference and research laboratories. Treatment is mainly supportive in immunocompetent patients, but cidofovir and IV immunoglobulins have been used in some immunocompromised patients.[114]

Influenza

Three antigenically distinct influenza viruses exist—types A, B, and C. All three have hemagglutinin surface antigen, but only types A and B have neuraminidase surface antigen. Antigenic drift for types A and B produces minor changes in the surface antigens, resulting in endemic illness. Antigenic shift only occurs with influenza type A, resulting in a major change or new surface antigen, for which there may be low or no immunity in the population. Influenza type A is subtyped by its surface antigens, and currently three influenza strains are circulating worldwide, including influenza A/H1N1, H1N2, and H3N2.[33,115]

Clinical signs of uncomplicated influenza pneumonia include coryzal symptoms followed by dyspnea, fever, cyanosis, cough, and wheezing. Children with influenza typically have a more sudden onset of “toxic” signs than do those with other viral diseases. Infection is associated with myalgia, encephalopathy, and cardiac involvement. Pathologically, influenza virus infection is similar to RSV in that the virus destroys ciliated respiratory epithelial cells with subsequent edema and an acute inflammatory response. Influenza has been associated with Reye syndrome and with significant bacterial suprainfections.[116] In patients in whom bacterial infection develops, there often is a period of apparent improvement before a sudden worsening that is heralded by the production of purulent sputum, return of fever, and development of pulmonary consolidation.[117] Fatal outcomes have been reported in previously healthy children, as well as in high-risk groups.

Prevention of influenza disease is possible with either administration of multivalent influenza vaccine (influenza A/H1N1, A/H3N2, and B) or chemoprophylaxis with oseltamivir and zanamivir (influenza A, B, and A/H1N1) or amantadine hydrochloride and its closely related analog rimantadine (influenza A). One study showed efficacy of aerosolized ribavirin in the treatment of persons with influenza B.[118,119] Diagnosis of influenza pneumonia may be made by a culture of the virus from respiratory secretions or with serologic techniques. Rapid diagnosis by means of immunofluorescence of exfoliated nasopharyngeal cells may be helpful, as well as by PCR. Treatment includes supportive care, monitoring of respiratory status, and administration of antiviral medications.

Measles

Measles is a highly contagious disease that is preventable by vaccine; the incidence

fell below the endemic threshold in the United States in 2000.[120] Endemic outbreaks continue in developing countries and when international travelers import measles to nonimmunized persons in the United States.[33,120] Typical disease manifests as high fever, cough, runny nose, and generalized rash. Respiratory symptoms are nearly universal in this illness, making the prevalence of measles pneumonia difficult to determine. Moist crackles develop in most children, and approximately 20% have expiratory wheezes and hypoxia. In cases in which radiographs have been obtained, a fine reticular infiltrate was present, compared with the nodular infiltrates in children with atypical measles. Although the clinical syndrome usually resolves over 1 to 2 weeks, both radiographic and pulmonary function abnormalities may persist for months. Severe life-threatening tracheitis may occur during the course of measles or bacterial suprainfection.[121-123] In fatal cases, severe respiratory and nervous system disease are manifested, and lung tissue demonstrating interstitial pneumonitis with diffuse endothelial cells, pneumatocyte degeneration, and presence of multinucleated giant cells has been reported.[124]

Diagnosis is made by isolation of the virus, standard serology, or identification of viral ribonucleic acid by reverse transcription PCR. All suspected cases should be reported to local and state health departments. No antiviral agent is available; treatment is supportive. Two doses of vitamin A (200,000 International Units on consecutive days) have been shown to reduce pulmonary-specific and overall mortality rates in patients up to 2 years of age.[125] Administration of IV immunoglobulin may be of benefit to high-risk or immunosuppressed patients when it is started within 6 days of exposure.[33]

Human Immunodeficiency Virus

HIV infection in children most commonly presents with recurrent bacterial infections. The major morbidity and mortality in pediatric AIDS are associated with lung disease, ranging from opportunistic infections such as *Pneumocystis carinii* pneumonia to entities such as chronic interstitial pneumonitis.[126,127] Treatment for specific pulmonary pathogens is discussed throughout this chapter, but specific guidelines for HIV/AIDS treatment are lengthy, rapidly changing, and beyond the scope of this chapter. \More specific and current information regarding HIV/AIDS is available at www.aidsinfo.nih.gov/guidelines. This website provides the most current information regarding HIV/AIDS clinical research, HIV treatment and prevention, and medical practice guidelines. This information can also be obtained by phone at 1-800-HIV-0440 within the United States or 1-301-315-2816 outside the United States or by mail at AIDS Info, P.O. Box 4780, Rockville, MD 20849-6303.

Complications

The actual mechanisms by which viruses predispose the lung to secondary bacterial infection are not precisely understood. Viruses are capable of altering both cellular and noncellular defenses of the respiratory tract.[52,53,128] Viral infection of the epithelial cells appears to predispose the upper respiratory tract mucosa to bacterial colonization by allowing bacterial pathogens to adhere to injured cells.[51,52] Viral infection may cause significant impairment of both intracellular killing and ingestion of bacteria by the pulmonary macrophage. Significant defects in polymorphonuclear leukocyte chemotaxis and phagolysosome fusion occur during acute viral infection.

The greatest impairment of macrophage function occurs 1 week after the onset of viral infection, which correlates with the peak incidence of bacterial suprainfection. Thus suprainfection during the course of viral lower respiratory tract disease appears to be the result of a combination of the cytopathic effects of the virus on the respiratory mucosa and various alterations in host immune response.

Significant life-threatening complications of viral lower respiratory tract disease are noted in Box 55.2. Respiratory failure with viral pneumonitis resembling ARDS is frequently seen in patients in the pediatric critical care unit. It is often associated with influenza or adenovirus but can occur with varicella, cytomegalovirus, and RSV.[60]

Box 55.2

Major Sequelae/Life-Threatening Complications Associated With Viral Pneumonitis

Subacute Sclerosing Panencephalitis: Measles

- Guillain-Barré syndrome: influenza, varicella
- Reye syndrome: influenza, VZV
- Encephalitis: adenovirus, measles, RSV, CMV
- Seizures: influenza
- Bacterial superinfection: influenza, VZV, Epstein-Barr virus, measles
- Asthma: RSV, parainfluenza, rhinovirus
- Apnea: RSV, influenza
- Bronchiolitis obliterans: influenza, adenovirus, measles
- Chronic obstructive pulmonary disease: RSV
- Fatal pneumonitis: influenza, measles, adenovirus, RSV, parainfluenza, CMV
- Tracheitis, life-threatening: measles, parainfluenza
- Appendicitis: adenovirus, measles
- Intussusception: adenovirus, CMV
- Hepatitis: adenovirus, influenza measles, CMV
- Nephritis: adenovirus, influenza, measles
- Myocarditis: adenovirus, influenza, measles
- Pericarditis: adenovirus, influenza, measles

- Arthritis: adenovirus
- Deafness: adenovirus
- Keratoconjunctivitis: adenovirus
- Myositis: influenza
- Stevens-Johnson syndrome: measles
- Coagulopathy: measles
- Thrombocytopenia: measles, CMV

CMV, cytomegalovirus; *RSV*, respiratory syncytial virus; *VZV*, *Varicella zoster* virus.

Diagnosis

A number of techniques are available for establishing a viral diagnosis. In the critical care setting, the decision to undertake these diagnostic measures should be guided by how awareness of the specific viral illness will affect the clinical management. Potential benefits include (1) a guide to selection of appropriate antiviral therapy and avoidance of unnecessary treatments with antibiotics and (2) initiation of appropriate infection control measures and use of vaccine or drug prophylaxis. Direct isolation of viruses is a sensitive method of diagnosis early in the course of disease when a large number of infectious particles are present in respiratory secretions. Nasopharyngeal washings are the preferred specimens for viral cultures because large quantities of secretions for culture are easily available. Unfortunately, viral isolation may require up to 2 weeks for positive culture results. Serologic testing or diagnosis depends on demonstration of a rising antibody titer between acute and convalescent sera. Although serologic data may provide a diagnosis, they are of little value in guiding therapeutic critical care interventions. The more commonly used methods for viral diagnosis involve detection of viral antigens present in the respiratory secretions. These antigen-detection techniques using radioimmune or enzyme-linked assays can detect all riboviruses and adenoviruses that commonly produce lower respiratory tract infections. Antibody detection has also been used successfully in the diagnosis of lower respiratory tract viral disease (cytomegalovirus pneumonia).[129] A major advantage of tests capable of detecting viral components is that these studies can be performed rapidly and the results made available to the critical care physician in hours, thus allowing timely management.

Prevention and Treatment

Guidelines for influenza chemoprophylaxis and treatment are lengthy and rapidly changing. Specific and current information regarding the use of antiviral drugs is available at www.aapredbook.org/flu or www.cdc.gov/flu/professionals/antivirals/index.htm.

Vaccination

Passive immunization is also available for some viruses that can be associated with pneumonitis, but recommendations are ever changing, so please check the Centers for Disease Control and Prevention (CDC) recommendations as well (see Table 55.3 for further details).

Chemoprophylaxis

Amantadine, rimantadine, oseltamivir, and zanamivir are approved for prophylaxis of viral respiratory tract infection caused by influenza. Amantadine and rimantadine have been shown to be effective prophylaxis for influenza type A; however, they are not active against influenza type A/H1N1 or influenza type B. Amantadine resistance has been reported in persons with influenza type A/H3N2. Oseltamivir and zanamivir have activity against influenza types A, B, and A/H1N1. Oseltamivir resistance has been reported among persons with influenza type A/H1N1 strains globally, but no significant resistance has been reported among persons with influenza type A/H1N1 strains circulating in the United States. All four drugs are recommended for persons at high risk for serious influenza infection who have not been vaccinated or who have received the vaccine within 2 weeks of the onset of an epidemic. They are also recommended for persons in whom appropriate immune response may not develop following vaccination and for persons who cannot receive the influenza vaccine because of allergic reactions.[33,130,131]

Therapy

A number of antiviral agents inhibit the replication of respiratory viruses in vitro, and some of these drugs have been used clinically in both experimental and naturally occurring respiratory infections (Table 55.5). Amantadine can be used to treat seasonal influenza A virus infections. Numerous studies have demonstrated that amantadine shortens the course of illness in uncomplicated influenza infections in otherwise healthy children if initiated within the first 48 hours of the disease. Amantadine is not effective against influenza type B or A/H1N1.[132] Currently circulating influenza A and H1N1 viruses are resistant to adamantanes, so these medications are not recommended for use currently. Most influenza A and B virus strains are susceptible to oseltamivir and zanamivir.[133] These neuraminidase inhibitors have been shown to reduce the severity and duration of illness.[134-137] Resistance to oseltamivir has been reported in persons with influenza type A/H1N1 strains but not A/H3N2 or B strains.[138-141] Zanamivir is effective against influenza type A, B, and A/H1N1, but it has not been approved for therapeutic use in children younger than 7 years.[33] Peramivir was approved to treat influenza infection in adults on December 19, 2014. Peramivir is the first neuraminidase inhibitor approved in the IV form. Peramivir is a neuraminidase inhibitor and should not be administered if the patient has a severe allergy to oseltamivir, zanamivir, or one of their metabolite components.[142] Resistance patterns are perpetually changing, and for the most up-to-date information regarding resistance patterns, see the CDC website at www.cdc.gov/flu/professionals/antivirals/.

TABLE 55.5

Antiviral Agents Used in Viral Pneumonia

Agent	Indication	Route	Side Effects
Acyclovir	HSV, varicella Prophylaxis/treatment	IV, PO	Phlebitis, seizures, leukopenia, renal dysfunction
Valacyclovir	HSV, varicella Prophylaxis/treatment	PO	Bone marrow suppression, renal failure
Ganciclovir	CMV in immunocompromised host Prophylaxis/treatment	IV, PO	Renal failure, bone marrow suppression, seizure
Valganciclovir	CMV prophylaxis	PO	Same as ganciclovir
Amantadine	Influenza A Prophylaxis/treatment	PO	Nausea, dizziness, ataxia, diarrhea
Rimantadine	Influenza A Prophylaxis	PO	Similar to amantadine
Zanamivir	Influenza A and B Treatment, prophylaxis under study	Diskhaler	Bronchospasm
Oseltamivir	Influenza A and B Prophylaxis/treatment	PO	Nausea, vomiting, vertigo
Peramivir	Influenza A and limited B treatment	IV	Stevens-Johnson syndrome, erythema multiforme, neuropsych events, and diarrhea
RSV-IVIG	RSV prophylaxis (high-risk population)	IV	Allergic, fluid overload, not approved for CCHD
Palivizumab	RSV prophylaxis	IM	Anaphylaxis
Ribavirin	RSV (parainfluenza, influenza A and B, measles)	Small-particle aerosol	Conjunctival edema
Foscarnet	CMV retinitis, HSV resistant to acyclovir	IV	Renal dysfunction, nausea, bone marrow suppression
Pieconaril (under investigation)	Enterovirus and rhinovirus Prophylaxis/treatment	PO	Under investigation

CCHD, cyanotic congenital heart disease; *CMV*, cytomegalovirus; *HSV*, herpes simplex virus; *IVIG*, intravenous immunoglobulin; *RSV*, respiratory syncytial virus.

Ribavirin is a synthetic nucleoside analog licensed for use in aerosol form for treatment of persons with severe RSV infection. This therapy may shorten the course of the illness and improve oxygenation in high-risk patients. A few children with severe combined immune deficiency have been treated with ribavirin with resulting clinical improvement and decrease in viral shedding.[65,143-153] Ribavirin aerosol may be effective in shortening the course of both influenza type A and B in infections in college students, and it is possible that parainfluenza and the measles virus can be treated with ribavirin.[154] Various case reports of treatment in seriously ill adults with complicated viral infections suggest that ribavirin may be an effective treatment. Overall, the documented therapeutic benefit of antiviral agents has been inconclusive. Improvement is most apparent when the therapy was initiated early after the onset of infection. Future investigations are necessary to define the optimum dose/route of antiviral agents for each respiratory virus/pneumonia and to clarify the ability of antiviral therapy to modify serious lower respiratory tract infection in high-risk infants and children.

In persons with varicella or zoster, acyclovir reduces the period of viral shedding and the time needed to heal skin lesions, and it can prevent dissemination of localized zoster in immunocompromised children. Thus the use of acyclovir in immunosuppressed patients can be justified by the low toxicity of the drug and potential severity of the illness. Ganciclovir (DHPG) is an antiviral drug with significant activity against cytomegalovirus.[155] It has been used successfully in immunocompromised patients with disseminated cytomegalovirus and pneumonia.[156] Symptomatic infection of the lower airway with herpes viruses is rare. When it occurs, it usually does so in an immunosuppressed child. Antiviral therapy for herpes viruses includes acyclovir, foscarnet, and adenine arabinoside.[157,158]

Fungal Pneumonitis

Fungal infections are becoming increasingly important in the differential diagnosis of pulmonary infections, particularly in immunocompromised hosts. The majority of pulmonary mycotic infections occur in two microbiologic and clinical groups (Box 55.3). In general, different patient groups are at risk for infection because of either opportunistic or pathogenic dimorphic pulmonary fungi. Primary pulmonary mycotic infections generally infect healthy children exposed to the pathogen in a particular geographic or environmental setting, whereas the opportunistic mycoses occur in children whose immunity is compromised.[159,160] The increase in opportunistic fungal infections can be attributed to numerous factors, including the following:

1. Selection of fungal organisms as flora by the use of broad-spectrum antibiotics

2. Leukopenia secondary to use of cytotoxic agents

3. Suppression of humoral and cell-mediated immunity by cytotoxic and suppressive therapy

4. Increased use of immunosuppressive drugs in patients with organ transplant or collagen vascular disease

5. An increasing number of patients with AIDS

6. An increased number of invasive surgical procedures in hospitalized children, which create portals of entry for fungi[19]

Box 55.3

Major Pulmonary Mycoses

Primary (Endemic; Pathogenic to Normal Children)

Dimorphic Soil

- Histoplasmosis
- Blastomycosis
- Coccidioidomycosis
- Paracoccidioidomycosis
- Sporotrichosis

Nondimorphic Soil

- Cryptococcosis

Opportunistic (Ubiquitous; Abnormal Host)

- Aspergillosis
- Mucormycosis
- Candidiasis

Primary Pulmonary Fungi

Fungi that cause primary pulmonary infection in otherwise healthy hosts are generally endemic mycoses found in a particular geographic distribution. The four major mycoses in this group are histoplasmosis, blastomycosis, coccidiomycosis, and paracoccidiomycosis.[161] Chemiluminescent DNA probes are available for identification of blastomycosis, coccidioidomycosis, and histoplasmosis. We review these primary pulmonary mycoses in the following section but exclude paracoccidiomycosis because this infection occurs primarily in South America, Central America, and Mexico. For information regarding paracoccidiomycosis infections, please refer to up-to-date journal articles.

Pathogenesis

The dimorphic fungi cause infection following inhalation of spores (conidia) into the pulmonary system. In the lower respiratory tract the conidia transform into the yeast phase, which is susceptible to phagocytosis by the pulmonary macrophages. These yeast forms may persist in the nonimmune host. As the yeast-laden macrophages are transported via the lymphatics to the peribronchial and mediastinal lymph nodes, hematogenous dissemination may occur. However, with the primary pulmonary infection in the immunocompetent host, extrapulmonary infection is rare.

Progressive primary pulmonary infection in the absence of host defenses (such as in a patient who is immunocompromised or an infant) may lead to seeding of extrapulmonary sites, dissemination, and death if left untreated. Cellular immunity is the primary host defense against these deep mycoses, many of which are subclinical and require no therapy. However, children with severe life-threatening infections should be treated (Table 55.6).

TABLE 55.6

Antifungal Therapy

Drug	Indications	Route	Side Effects
AmB	All life-threatening mycoses, empiric therapy in febrile granulocytopenic patients	IV	Fever, chills, nephrotoxicity, anemia, hypokalemia, thrombophlebitis
AmB lipid complex, AmB cholesteryl sulfate, AmB liposomal	Failure or intolerance to AmB, organ transplantation with renal insufficiency	IV	Same as AmB with decreased nephrotoxicity and infusion-related adverse events
Flucytosine (5-FC)	With AmB for life-threatening infections with *Cryptococcus, Candida* (central nervous system, ophthalmitis, disseminated, renal) or invasive disease refractory to AmB	PO	Neutropenia with elevated serum levels (if levels are not available, this agent should not be used)
Ketoconazole	Not indicated for acute treatment of severe invasive disease; alternative for mild blastomycosis, histoplasmosis, *Candida*, or coccidiomycosis	PO	Nausea, vomiting, hepatotoxicity, testosterone synthesis blockade
Miconazole	Deep infection: *Pseudallescheria* and *Scedosporium*	IV	Cardiac dysrhythmias,

			cardiovascular collapse with rapid infusion
Fluconazole	*Cryptococcus, Candida* (question in critically ill), coccidiomycosis	PO	Nausea, vomiting, dizziness
Itraconazole	Non–life-threatening blastomycosis, sporotrichosis, histoplasmosis, paracoccidioidomycosis	PO	Pediatric dosage not yet established; nausea, hypokalemia, edema, hypertension, adrenal insufficiency, epigastric pain
Voriconazole	*Aspergillus* and *Cryptococcus,* resistant *Candida* spp.	IV	Visual changes, fever, nausea, vomiting, elevated liver enzymes
Caspofungin	Treatment for resistant *Aspergillus* and possible combination therapy for *Candida* and endemic mycoses	IV	Fever, phlebitis, nausea, headache, elevated liver enzymes
Mycamine	*Candida*	IV	Fever, nausea, vomiting, hemolysis, elevated liver enzymes
Posaconazole	*Candida* *Aspergillus* *Zygomycetes*	PO	Fever, headache, prolonged QT, elevated liver enzymes, renal impairment, increased midazolam levels if used together

AmB, amphotericin B.

Histoplasmosis

Histoplasmosis is caused by *Histoplasma capsulatum,* which is endemic in the east-central United States, particularly the Mississippi and Ohio River valleys. Primary pulmonary histoplasmosis is asymptomatic in more than 50% of patients. Patients usually become ill 2 weeks following exposure, manifesting influenza-like illness with fever, chills, myalgia, headache, and a nonproductive cough. Occasionally children have a skin rash, arthritis, and erythema nodosum.

The chest radiograph may show patchy areas of pneumonitis and prominent hilar adenopathy. After exposure to an usually heavy inoculum, a more diffuse pulmonary involvement may occur with extensive nodular infiltrates. Children with this condition frequently have significant dyspnea and may progress to respiratory failure. The chest radiograph frequently returns to normal after a primary pulmonary infection; however, a number of residual abnormalities may be seen, including multiple nodules with a dense core of calcium (a target lesion), scattered calcifications within lymph nodes, and occasionally small "buckshot" calcifications scattered throughout both lung fields.[161]

Diagnosis

The skin test is of epidemiologic value but is useless in individual case diagnosis because a positive test only indicates prior exposure to this disease. Neither are direct smears of the sputum helpful for diagnosis. Most cases are recognized by serologic studies and include immunodiffusion (M and H bands) and complement fixation. Unfortunately, the immune diffusion test is relatively insensitive, and a response may be delayed following a primary infection. The complement fixation test is more sensitive but less specific.[162] A titer of 1 : 32 or higher against the yeast antigen is diagnostic if the clinical picture suggests histoplasmosis. Children with rapidly progressive pneumonia that is not responding to antibacterial antibiotic therapy or those in impending respiratory failure need urgent diagnosis, and invasive procedures such as BAL, diagnostic lung aspiration, or open lung biopsy are necessary to obtain the required information.

Complications

Disseminated histoplasmosis refers to progressive extrapulmonary infection that occurs most frequently in children younger than 2 years and in patients with altered cellular immunity.[17,163] The clinical features of disseminated disease include fever, weight loss, hepatosplenomegaly, cough, diarrhea, gastrointestinal ulcers, and skin lesions. Anemia, leukopenia, and thrombocytopenia may occur as a result of bone marrow involvement in young children and may lead to rapid death. Chronic disseminated disease, which is uncommon and insidious, may present as a nonspecific afebrile illness without cough or radiographic abnormalities. Occasionally, disseminated histoplasmosis presents as a localized infection involving the CNS. Chorioretinitis and pleural effusion, along with isolated gastrointestinal findings involving terminal ileum, can occur.

Treatment

The usual primary pulmonary infection requires no treatment. Amphotericin B should be used for persons with a severe infection, especially if it is life threatening or associated with respiratory failure. Upon clinical improvement, itraconazole should be given to complete the course of therapy. Chronic cavitary histoplasmosis can be treated with IV amphotericin B or a long-term course of oral itraconazole or ketoconazole. Pericarditis therapy should include antiinflammatory agents such as indomethacin or aspirin. Failure of pericarditis to improve with nonsteroidal antiinflammatory medication should not prevent use of a brief course of steroids because steroid use does not appear to predispose to dissemination.[164-168]

Blastomycosis

Blastomycosis is endemic to the southeastern region of the United States but extends northward along the western shores of Lake Michigan across to northern Wisconsin and Minnesota and into Canada. An intimate exposure to an infected site is required for infection rather than the casual exposure often found with histoplasmosis and coccidioidomycosis.[169-171] Most pediatric cases of blastomycosis occur in older children and adolescents in rural areas.

The pathophysiology is similar to that of histoplasmosis. The clinical course of primary pulmonary blastomycosis is variable. The symptoms are similar to those of acute bacterial pneumonia and include high fever, cough with productive purulent sputum, occasional pleuritic chest pain, and myalgias. Such symptoms generally last 2 to 3 weeks.

The chest radiograph frequently demonstrates patchy areas of alveolar consolidation affecting one or both lower lobes. Pleural effusions and cavitation can occur but are unusual. A rather dense lobar infiltrate similar to pneumococcal pneumonia is uncommon but occurs more frequently in pulmonary blastomycosis than with other pulmonary fungi. Clearing of the chest x-ray film may take 3 to 4 months.

Blastomycosis is not always self-limited, and progressive pulmonary infection can occur with acute dissemination to distant sites. In such instances the child remains febrile and toxic with rather rapid progression. Diffuse pulmonary involvement with acute miliary spread can lead to rapid respiratory failure and radiographic findings of ARDS.

Children may have asymptomatic primary pulmonary blastomycosis that is

diagnosed only with reactivation blastomycosis involving the skin, bones, or other distant organ sites. Reactivation blastomycosis appears to be most common in the first 1 or 2 years immediately after the initial pulmonary infection and probably occurs in less than 5% of all infected patients. A chronic form of pulmonary blastomycosis may occur in patients who have no significant history of acute pneumonia but present with respiratory symptoms that have persisted for weeks or months. These persons have a chronic cough, productive sputum, nocturnal fevers, night sweats, weight loss, and dyspnea. Chest radiographs in persons with chronic blastomycosis may reveal a single large mass, often perihilar in location. A more common finding is a fibronodular infiltrate with small cavities and fibrosis radiating toward the hila. Such findings mimic tuberculosis.

Diagnosis

No reliable skin test exists for pulmonary blastomycosis. Sputum and material aspirated from BAL, lung aspiration, skin, or bone lesions may be examined directly after potassium hydroxide digestion, and the pathognomonic yeast forms are identified. Such positive direct smears provide a rapid, accurate, inexpensive test. Serologic tests include immunodiffusion using purified antigen. The complement fixation test is less sensitive and less specific than the immunodiffusion test.[172] Most acute cases are diagnosed by direct sputum smears or from BAL.

Complications

Patients whose illnesses are clinically similar to bacterial pneumonia frequently have a self-limited process. Life-threatening progressive respiratory failure similar to ARDS can occur. In such instances, diagnosis and therapy including mechanical ventilation must be initiated promptly. Dissemination occurs only in the most severe cases.[173,174] With dissemination, characteristic skin lesions (ie, raised and crusted) may occur on the face and upper extremities. In persons with disseminated disease, bone involvement often includes the spine, ribs, and skull.

Treatment

Acute pulmonary blastomycosis does not require treatment in all cases. Treatment with IV amphotericin should be given if the patient is severely ill or if progressive illness occurs. Oral itraconazole and ketoconazole have been used for treatment of chronic pulmonary blastomycosis (similar to tuberculosis) but should not be used for severe life-threatening infections.[175,176]

Coccidioidomycosis

Coccidioidomycosis is a relatively common infection that occurs primarily in the southwestern United States. Sixty percent of patients with primary pulmonary infection have no symptoms or minimal symptoms. Children 5 years or younger have a higher frequency of progressive disease than do older children and healthy adults. The clinical course of coccidioidomycosis is a flulike illness usually associated with fever, cough, and chest pain. There may be a transient maculopapular eruption similar to erythema nodosum in children. Radiographic abnormalities range from hilar adenopathy to patchy infiltrates with pleural effusion.

Diagnosis

Diagnostic studies include skin testing, which has some usefulness if the patient has compatible respiratory illness and a past negative skin test. Direct smears of potassium hydroxide–digested sputum are helpful if characteristic spherules are found. Antibody detection through complement fixation may be a useful measure of severity of disease.[174] In cases of suspected coccidioidal meningitis, complement fixation tests on cerebrospinal fluid should be obtained because many patients have a negative spinal fluid culture with positive complement fixation studies. Use of chemiluminescent DNA probes may aid in rapid diagnosis.

Complications

Complications include chronic progressive coccidioidal pneumonia, which is similar to tuberculosis but uncommon in pediatric patients. Disseminated coccidioidomycosis does occur and is often accompanied by persistent fever and rapid progression with development of meningitis, bony lesions, and skin and soft tissue disease. A fulminant primary miliary spread of disease with severe respiratory failure and diffuse lung involvement has been observed in patients with altered immune status. The disseminated disease frequently has an insidious onset, following the primary pulmonary infection by weeks. The meninges are the most worrisome site of extrapulmonary involvement because coccidioidal meningitis requires intrathecal amphotericin B therapy, and cure is unlikely.[177,178]

Treatment

If the infection causes prolonged fever, progressive pulmonary disease, significant mediastinal adenopathy, or disseminated lesions, antifungal therapy with amphotericin B should be initiated. Ketoconazole has been used in skeletal, cutaneous, and other localized infection but not for meningitis. Coccidiomeningitis is the most difficult complication of this disease to treat; it requires intrathecal and systemic therapy with amphotericin B.[179-181]

Opportunistic Pulmonary Mycoses

Pulmonary Aspergillosis

Invasive pulmonary aspergillosis occurs almost exclusively in immunocompromised patients.[15,182-185] Despite treatment, unless the underlying immune defect is ameliorated, invasive pulmonary aspergillosis is often fatal. Many cases are nosocomially acquired, usually in hospitals undergoing renovation or new construction.[171] Children with hematologic malignancies (eg, myelogenous and lymphocytic leukemia) or organ transplantation are at the highest risk for development of invasive disease, presumably because of the abnormal immune cells and the cyclic neutropenia induced by repeated doses of chemotherapy. Persons with heart and bone marrow transplants are at higher risk for aspergillosis infection than are persons with kidney transplants.

Neutropenia is an important risk factor for the development of aspergillosis because both the absolute neutrophil count and the duration of neutropenia have been related to the incidence of infection. Use of steroids and immunosuppressive

drugs also appears to predispose to invasive aspergillosis.[186] Immune and myelosuppressed patients exposed to heavy aerosol concentrations of aspergillosis spores have an increased chance of the development of invasive pneumonia. Efforts should be made to eliminate the risk of airborne conidiospores in patient areas. If such elimination is not possible, then susceptible patients should be moved away from areas of excavation or construction.

Clinical signs of invasive aspergillosis are nonspecific. The usual presentation includes pulmonary infiltrates and fever that do not respond to empiric antibacterial therapy. Patients may exhibit dyspnea, a nonproductive cough, pleuritic chest pain, and pleural friction rubs. Symptoms are usually difficult to identify in small children, and auscultatory changes are typically found only with advanced disease. Hemoptysis is uncommon in children.

Diagnosis

Radiographs of the chest reveal virtually any infiltrative pattern, including patchy infiltrates, necrotizing pneumonitis, miliary nodules, and lung abscesses. Early findings may include a round, patchy pneumonia that progresses to a wedge-shaped density characteristic of pulmonary infarctions.[187] Definitive diagnosis of invasive pulmonary aspergillosis requires histopathologic identification of fungus in tissue specimens. Positive sputum cultures do not prove the presence of invasive disease even in compromised hosts, although isolation should be taken seriously and multiple positive cultures should be considered strong evidence of fungal infection in patients whose immunity is compromised. Serologic antibody tests have no value in the diagnosis of invasive aspergillosis. In severely ill children, fiberoptic bronchoscopy with bronchial lavage is the initial diagnostic test of choice in patients with suspected pneumonitis. If the results of fiberoptic bronchoscopy are nondiagnostic, a lung biopsy (open or needle) may be required, though not often done. Enzyme immunoassay detecting galactomannan antigen, a constituent of the *Aspergillus* cell wall, may aid in the diagnosis. Sensitivity and specificity of this test depends on many factors.[188] This assay may be run on blood or BAL specimens, and this along with cultures and CT findings may aid in the diagnosis of aspergillosis without requiring a biopsy specimen.

Complications

Untreated invasive pulmonary aspergillosis is usually fatal in immunocompromised patients. Fatality rates greater than 80% are reported; however, survival may improve if appropriate therapy is initiated early in the disease. Death usually results from progressive pneumonitis, pulmonary infarction, and massive hemoptysis. On rare occasions, endocarditis, osteomyelitis, meningitis, or infection of the eye or orbit occurs.

Treatment

Therapy with amphotericin B should be initiated early in the course of the disease. Surgical resection is usually not indicated in the treatment of critically ill patients with uncontrolled disease. However, it may be considered in patients who have only partial response to antifungal therapy or with relapsing disease in a well-defined lung segment or in those identified with massive hemoptysis. In critically ill patients

who are unresponsive to therapy or in whom aspergillosis develops while they are receiving amphotericin B, the addition of flucytosine or rifampin may be helpful. Use of the lipid formulations of amphotericin is indicated in patients who are intolerant of or refractory to conventional amphotericin for reasons such as renal toxicity or persistent infusion-related adverse events. Itraconazole is an option for use after an initial course of amphotericin B. Change from amphotericin to the oral itraconazole must take into account the patient's status.[189-190] New antifungal agents such as voriconazole and micafungin have shown effectiveness in treating aspergillosis.[191-193]

Pulmonary Candidiasis

Of all the opportunistic pulmonary mycoses, candidiasis may be the most difficult to diagnosis and treat effectively because the *Candida* organism routinely colonizes the upper respiratory tract, resulting in positive cultures without significant disease. The prevalence of *Candida pneumonitis* has increased remarkably in the past 3 decades as a result of the increased use of broad-spectrum antibiotic therapy, immunosuppressive drugs, indwelling vascular lines, prosthetic devices, and organ transplantation.

Pathogenesis

Pulmonary candidiasis may occur by hematogenous seeding of the lung parenchyma from a distal infected site or through direct invasion of inhaled or aspirated organisms. *Candida* acquired through the hematogenous route demonstrates pulmonary lesions that are diffuse, bilateral, and miliary. The endobronchial form of infection does not have a significant interstitial component such as that seen with a hematogenous form. The endobronchial form radiographically demonstrates pulmonary lesions that are small, asymmetrical, patchy, and frequently found in the lower lobes.

Diagnosis

There are no pathognomonic signs and symptoms of pulmonary candidiasis. The diagnosis should be considered in an immunocompromised febrile patient with a pulmonary lesion, particularly if broad-spectrum antibiotics were used without a response. Oral pharyngeal involvement (thrush) indicates that the patient is harboring the organism in an invasive stage. Retinal lesions on ophthalmoscopic examination may help identify invasive *Candida*. A cutaneous lesion often seen in persons with invasive *Candida* is a discrete erythematous papule with an erythematous halo. The radiographic findings of *Candida* pneumonia are nonspecific. Early in the course of infection, patients have normal chest radiographs. The isolation of *Candida* in culture from an otherwise sterile body fluid or tissue and the identification of the organism in a biopsy specimen are diagnostic of invasive *Candida*. Serologic studies are of no diagnostic value. Proof of *Candida* pneumonia requires tissue examination or evaluation of alveolar lavage or protected brush samples from bronchoscopy as direct evidence of tissue invasion. If these studies fail to identify the disease process, the diagnosis of pulmonary candidiasis may be established with a lung biopsy.

Complications

As with other mycoses, pulmonary candidiasis may be complicated by systemic dissemination affecting other organs. Concomitant infection with other organisms, particularly bacteria, is not uncommon.

Treatment

Effective treatment includes correction of the patient's immunosuppression in addition to administration of amphotericin B. The concomitant and synergistic effect of flucytosine has been demonstrated with amphotericin B for most *Candida* species and is recommended for use in critically ill patients.

Pneumocystis carinii Pneumonia

Pneumocystis carinii, which is probably a protozoan, produces a unique infection. In the early stages of the infection with cysts, trophozoites are found distributed within the alveoli, most commonly adjacent to the alveolar septum. Usually in this phase, no clinical signs or symptoms are evident. With extension of infection, the number of organisms increases and bilateral diffuse distribution occurs throughout the lungs. Eventually desquamation of the alveolar septal cells occurs, with subsequent phagocytosis of the organisms by the alveolar macrophages. Minimal inflammation occurs in discrete areas of the alveolar septum at this stage of the disease, and a child may or may not be symptomatic. Ultimately the alveolar septum becomes thickened with inflammatory cells producing the clinical manifestations of childhood pneumocystosis.[194] In the infantile form there is extensive involvement of alveolar septa with plasma cell and lymphocyte infiltration. The normal septal thickness may be increased 5 to 20 times, which results in occupation of much of the alveolus by the distended septum.

Clinical Features

The three forms of disease patterns in pneumocystosis are the childhood/adult form, the infantile form, and a more chronic fibrosing form observed in some HIV-infected patients.[195] The typical child/adult type of pneumocystosis occurs in children beyond infancy who have congenital or acquired immunodeficiency disorders or malignancies and in organ transplant recipients.[196-198] Clinical symptoms of pneumonitis include fever, cough, tachypnea, cyanosis, flaring of the nasal ala, and retractions. Chest auscultation usually reveals no adventitious sounds until the terminal stage of infection, at which time bilateral crackles may be present. The chest roentgenogram initially may be normal, and changes may be seen only late in the course of the disease.[199]

In the infantile form of pneumocystosis, symptoms often begin insidiously and presentations include poor feeding, failure to thrive, and diarrhea. Increasing tachypnea may be detected, with respiratory rates frequently in the range of 80 to 120 breaths per minute. A dry, nonproductive cough with increased retractions and flaring of the nasal alae becomes prominent. Diffuse crackles may be heard bilaterally on auscultation of the chest, and most infants remain afebrile. The clinical course in neonates and infants may be quite rapid, with progressive cyanosis and

death resulting from respiratory failure within days. More commonly, however, the course extends over a period of several weeks, with a mortality rate varying from 20% to 50% without treatment.[198,200]

The chronic fibrosing type of *Pneumocystis* pneumonia identified in patients with HIV is associated with the presence of long-standing symptoms, localized radiologic changes, and interstitial fibrosis.[195]

Diagnosis

A definitive diagnosis requires documentation of *P. carinii* in lung tissue. The standard surgical open lung biopsy provides histologic details; however, the necessity for general anesthesia presents additional risk, particularly in the critically ill child. Identification of the organism in sputum is sufficient for the diagnosis, but inducing and obtaining sputum in young children are often difficult; in such cases, bronchoscopy should be considered.[201] Fiberoptic bronchoscopy with BAL, although not achieving yields as high as open lung biopsy, offers a useful and safe alternative to open lung biopsy.[9,10,29] Transthoracic percutaneous needle aspirate and thoracoscopy have been used successfully and can be obtained without the use of a general anesthetic.[202,203] However, pneumothorax can be expected in up to 30% of children. Once a specimen is obtained, it can be stained with one of the array of preparations by which the organism can be confidently identified. PCR techniques amplifying *P. carinii* DNA have been shown to be sensitive, and specific detection methods can be applied to BAL samples, sputum, and nasopharyngeal aspirates with success.[204] Serum lactate dehydrogenase is usually elevated in patients with *P. carinii* pneumonia and appears to be related to the degree of lung injury.[205] The chest radiograph often may be normal early in the course of *P. carinii* pneumonia. However, as the disease progresses, the pattern demonstrates a diffuse bilateral alveolar disease process with hyperinflation and eventually development of air bronchograms. The bilateral densities are frequently more intense in the middle and lower lung fields. Only late in the course of disease do the upper lung fields become involved. Atypical lesions have been reported, including pneumonitis limited to lobar areas. Pneumatoceles and pleural effusions have been reported.[206]

Complications

P. carinii usually remains localized to the lungs, even with extensive disease. A disseminated form has been documented, with recovery of the organism from extrapulmonary sites including bone marrow, liver, and spleen. Life-threatening complications that can arise in patients with *P. carinii* pneumonitis include pneumothorax and pneumomediastinum. Pneumothorax, both spontaneous and iatrogenic, occurs frequently in patients with *P. carinii* pneumonitis. Some evidence indicates that upper lobe predominance of pneumothorax may be more frequent in those previously treated with inhaled pentamidine. Pneumomediastinum, with associated respiratory failure, may be noted in patients receiving assisted ventilation.

Treatment

Therapy for *P. carinii* should include specific anti-*Pneumocystis* chemotherapy,

inhibition of the pulmonary inflammatory response, and enhancement of the immunologic status of the patient.[207-212] Several drugs have been used for treatment of pneumocystosis (Table 55.7).

TABLE 55.7

***Pneumocystis Carinii* Pneumonitis Therapy**

Drug	Route	Duration of Therapy (Days)	Comments
TMP-SMX	IV/PO	21	DOC
Pentamidine isethionate	IV	21	DOC
TMP dapsone	PO	21	Alternative
Trimetrexate folinic acid	IV	21	Alternative
Clindamycin primaquine	PO	21	Alternative
Atovaquone	PO	21	Alternative
Prednisone	IV/PO	21	Adjunctive agent

DOC, drug of choice; *IV*, intravenous; *PO*, by mouth; *TMP-SMX*, trimethoprim-sulfamethoxazole.

Trimethoprim-sulfamethoxazole may be administered either orally or intravenously and is the drug of choice for treatment of this disease.[3,180] The second most widely used drug for treatment of *P. carinii* pneumonitis is pentamidine isethionate.[211,212] Its effectiveness has been well documented over several years, but it has an increased number of undesirable adverse effects and treatment failures compared with trimethoprim-sulfamethoxazole.[197] Secondary to the prevalence of sulfa allergy and therefore a need for an alternative therapy for *P. carinii,* pneumonitis studies continue to find new medication regimens and new medications that may be used as alternatives to trimethoprim-sulfamethoxazole. They all have their own side effect profile and their own risk benefit profile.[213-215] Administration of a corticosteroid such as prednisone should occur at the initiation of specific anti-*Pneumocystis* therapy to improve survival and attenuate or prevent the initial decline in oxygenation. In addition to the specific therapies, efforts should be made to reverse the immune dysfunction that allowed occurrence of *P. carinii* (ie, reduce or discontinue immunosuppressive medications).

Chemical Pneumonitis

A large number of chemical and physical agents may produce intense inflammation of the lower respiratory tract in children. Chemical pneumonitis and/or pneumonia may be acquired in several different ways, such as by aspiration, inhalation, ingestion, or injection.

Aspiration Pneumonia

Aspiration pneumonia is composed of a diverse group of disorders that have in common the soiling of the lower respiratory tract by foreign, nongaseous substances. For purposes of this chapter, neither the solid foreign body nor the infectious component of aspiration is discussed.

Gastroesophageal reflux (GER) has been defined as the retrograde passage of stomach contents into the esophagus. This condition may be asymptomatic or associated with significant regurgitation and vomiting, esophagitis, failure to thrive, and anemia.[216] Aspiration into the pulmonary tree can cause significant

complications including apnea, pulmonary fibrosis, severe necrotizing pneumonias, recurrent bronchospasm, and death. Diminished lower esophageal sphincter pressure is often the result of physiologic immaturity; hence GER is more frequent in younger infants. This disorder also occurs in older children, especially those with central nervous and neuromuscular dysfunction. Other high-risk pediatric populations include patients with congenital abnormalities of the tracheal-bronchial tree and those with severe chronic pulmonary disease (Box 55.4).

Box 55.4

Pulmonary Aspiration and Gastroesophageal Reflux: Associated Disorders

Associated Disorders

- Bronchopulmonary dysplasia
- Asthma
- Cystic fibrosis
- Infantile apnea

Central Nervous System

- Convulsive disorders
- Anoxic encephalopathy
- Neurologic impairment
- Myopathies

Congenital Malformations

- Tracheoesophageal fistula
- Hiatal hernia

General

- Failure to thrive
- Achalasia
- Cardiopulmonary resuscitation
- Emergency surgery

Pathophysiology

The association of GER and lung disease has been well documented; however, the actual cause and effect of the relationship has not been firmly established. Massive aspiration of gastric fluid produces direct injury to the mucosal surface of the respiratory tract, resulting in diffuse alveolar damage, hemorrhage, and necrotizing bronchiolitis. This may be followed by a rapid interstitial reaction, resulting in an acute inflammatory polymorphonuclear cell infiltration involving the interalveolar septa. Bronchiolitis obliterans and fibrosis can occur. In severe instances the initial onset of disease closely resembles that of ARDS with similar outcomes. Repeated aspiration of small amounts of gastric contents may lead to recurrent pneumonia, airway hyperreactivity, bronchitis, and bronchiectasis with eventual fibrosis and involvement of the pulmonary interstitium.

Clinical Findings

Clinical symptoms of GER vary with age.[216,217] In older children, heartburn, acid/bitter taste, retrosternal pain, or abdominal pain may be reported. Infants may be irritable and exhibit stridor, poor sleeping patterns, or intermittent apnea. Esophagitis can lead to microcytic anemia because of repeated episodes of gastrointestinal blood loss. Chronic respiratory symptoms may include coughing, wheezing with choking episodes occasionally resulting in apnea, or life-threatening events similar to those seen in infants with sudden infant death syndrome. In the hospitalized pediatric patient, significant aspirations may occur during or after general anesthesia. Severe aspiration may be seen in patients receiving tube feedings as a result of displacement of the feeding catheter.

Findings on a chest radiograph may vary from slight hyperinflation to a pattern of diffuse interstitial and alveolar densities. In mild cases a picture of bilateral diffuse infiltrates compatible with ARDS may be seen. Although a barium esophagogram can help to evaluate esophageal motility and detect esophagitis, it reflects only a single point in time. Therefore a negative study does not rule out the presence of GER. Radionuclide scans permit observation of esophageal function following administration of a radioactive tracer. Thus the frequency and severity of reflux and information on esophageal and gastric dysmotility may be obtained. If delayed aspiration occurs, the radionuclide may be observed in the lung fields on a delayed scan.[217] Esophageal motility and intraluminal pressures may be measured by esophageal manometry. Intraesophageal pH measurement is helpful in that it allows long-term monitoring of acid reflux by detecting frequency, duration, and intensity of reflux.[218,219] Esophagoscopy is also useful for assessing the extent of mucosal injury by allowing direct visualization and obtaining a mucosal biopsy. Use of BAL for assessment of lipid-laden macrophages has been useful in establishing or corroborating the diagnosis of aspiration in complex patients.[218,219]

Treatment

Treatment of patients with GER frequently includes placing the patient in an upright prone position and using thickened feedings. Use of antacid preparations, omeprazole, cimetidine, ranitidine, and other inhibitors of H_2 gastroreceptors may be helpful in decreasing acid production and neutralizing its effects on the esophageal mucosa. Omeprazole has on rare occasions been associated with electrolyte disturbances. It has also been reported to possibly result in atrophic gastritis with

prolonged use, but its use continues to increase despite these possible adverse effects.[220-224] Metoclopramide is used before meals to help improve lower esophageal function and aid gastric emptying. With the suspension of cisapride from the marketplace as an effective prokinetic agent because of potentially fatal toxicity, interest in erythromycin as a prokinetic agent has resurfaced, and many trials evaluating its dose and efficacy are under way.[225] Bronchodilators are used frequently to treat bronchospasm associated with GER. Because theophylline decreases the lower esophageal sphincter pressure, aerosolized β_2-agonists are preferred. In instances where medical therapy was attempted and failed or in life-threatening situations, antireflux surgery is indicated. In such instances a fundoplication, partial plication, or percutaneous gastrojejunostomy is the appropriate treatment of choice.[216] The most favorable outcome and lowest incidence of morbidity in such instances are achieved when surgery is delayed until the patient is adequately nourished and optimal pulmonary status has been obtained.

Inhalation Injury

Acute inhalation injuries are a leading cause of fatalities in pediatric patients. Smoke inhalation accounts for the largest number of pediatric lives lost to inhalation injury each year. A significant number of inhalation injuries as a result of irritant gases occur through industrial or household accidents.[226,227] Serious pulmonary inhalation injury may be manifested immediately or delayed in onset (Table 55.8).[228-230]

TABLE 55.8

Irritant Gases

Agent	Exposure/Environment
Direct Mucosal Injury	
Acrolein	Plastic, rubber, textiles
Ammonia	Fertilizer, refrigerants, explosives
Chlorine	Bleaching, disinfectant
Formaldehyde	Disinfectant, paper, photography
Hydrogen chloride	Refining, dye making
Hydrogen fluoride	Etching, petroleum
Nitrogen dioxide	Welding, fertilizer, farming
Phosgene	Insecticide, dyes, chemicals
Sulfur dioxide	Bleaching, refrigeration
Asphyxiation Injury	
Carbon dioxide	Mining, foundry
Carbon monoxide	Smoke, foundry, mining
Natural gas	Mining, petroleum

Pathogenesis

Direct injury to the mucosal surface is the most common mode of pulmonary injury. Inhalation of noxious substances may cause extensive physical damage to the lungs and seriously impair subsequent gas exchange. The epithelial cells of air passages may become necrotic and desquamate, causing marked airway obstruction. Bronchospasm caused by irritation from the inhaled gases or particles may lead to further airway obstruction. Severe damage to the basement membrane may occur and cause subsequent leakage of intravascular fluid and blood into the alveolar and interstitial spaces. Injury may occur at all levels of the respiratory tract, depending

on the physical and chemical properties of the irritant, the agent concentration, duration of exposure, and breathing pattern of the person exposed.[228,231,232] The clinical course usually has three phases: (1) the acute phase, which occurs within minutes or hours of the insult, resulting in pulmonary edema, hypoxemia, and respiratory failure; (2) the delayed phase, which occurs within the first few days and may include continuing effects of the lung injury such as pulmonary edema, airway obstruction, and superinfection; and (3) the phase in which long-term sequelae may be noted because of the hypoxic or ischemic injury to other organ systems and recurrent pulmonary problems resulting from reactive airways disease or interstitial fibrosis.

Clinical Findings

Clinical manifestations are nonspecific for inhalation of various irritant gases and may differ, depending on the individual child. Injury of the airways may be manifested as upper airway obstruction resulting in laryngotracheitis, bronchitis, and upper airway edema. More peripheral airway obstruction may present with classic findings of asthma and airway edema with hypersecretion. In cases of massive exposure the presenting symptoms may be those associated with acute respiratory distress syndrome, manifested by profound V/Q mismatch, cyanosis, dyspnea, and respiratory failure. Severe nasopharyngeal and laryngeal edema with hypersecretion may present as stridor.[229,231] Chest radiograph findings are nonspecific, ranging from scattered areas of atelectasis and infiltrate to dense bilateral alveolar infiltrates.

Treatment

Prompt physical removal from the offending agent and maintenance of upper airway patency are imperative. Endotracheal intubation is a high-risk procedure, and meticulous attention must be directed toward maintaining proper pulmonary toilet and removal of upper airway secretions and debris from the artificial airway once it is secured.

Oxygenation should be monitored closely. High oxygen concentrations, mechanical ventilation, and use of positive end-expiratory pressure may be necessary in the event of acute respiratory failure because the diminished compliance and formation of pulmonary edema occur rapidly. Use of steroids may be justified in the treatment of patients who have been exposed to oxides of nitrogen; however, use after exposure to other irritant gases has not been validated.

Bronchoscopy may be indicated and useful in assessing the severity of airway injury and as an aid to endotracheal intubation and treatment of major areas of atelectasis. However, use of BAL is usually not indicated except in instances in which significant particulate or carbonaceous material is likely. Humidification of air and oxygen mixtures to thin secretions is necessary, and chest percussion/postural drainage may help to mechanically clear the airways.

Use of prophylactic antibiotics in persons with inhalation injuries is not recommended. If pulmonary infection is suspected, prompt therapy with broad-spectrum antimicrobial agents should be started. Use of bronchodilators is advocated because of a high incidence of bronchospasm. No critical studies have evaluated this therapy in persons with an inhalation injury; however, the risk

associated with its use is low, and administration to the child with obvious airflow obstruction is warranted. Use of aerosolized β_2-agonists is preferred. Special attention is required in the presence of smoke inhalation with regard to treatment of carbon monoxide poisoning. Hyperbaric oxygen, if available, or sustained administration of 100% oxygen is recommended in the initial treatment of patients with significant carbon monoxide intoxication. Development of upper or lower airway edema may necessitate intubation and mechanical ventilatory support.[228,232,233] Administration of artificial surfactant may be beneficial in patients in whom ARDS develops.[233] Use of prophylactic steroids and antibiotics for persons affected by smoke inhalation is not recommended, especially if burn injuries are present, because complications are more frequent.

Prognosis

The prognosis of children with acute pulmonary injury produced by inhalation of toxic gases is generally good. Restrictive and obstructive pulmonary function abnormalities have been observed following recovery. Residual defects such as bronchiolitis obliterans, bronchiectasis, and reactive airways disease have been observed following smoke inhalation.

Ingestion/Injection of Pharmacologic Agents

Several chemotherapeutic agents and other commonly used drugs have potentially serious pulmonary toxicity (Box 55.5). Pulmonary toxicity is thought to be a direct effect in most instances, but immunologic and hypersensitivity mechanisms may also be involved. Toxicity may occur during therapy or after discontinuation of the agent.[234] The development of blebs in the capillary endothelium is followed by an interstitial fibrinous edema and mononuclear cell response with eventual hyaline membrane formation. Some studies have shown a significant decrease in type 1 pneumocytes with evolution of type 2 pneumocytes, septal thickening, and a proliferation of fibrous tissue with a decrease in the number of alveolar septa. Pleural thickening may accompany the pneumonitis.

Box 55.5

Pharmacologic Agents Associated With Pulmonary Toxicity

Cytotoxic Agents

Antibiotics

- Bleomycin: IP/PF, H, PEFF
- Mitomycin C: IP/PF, PE, PEFF

Alkylating Agents

- Cyclophosphamide: IP/PF, PE, B

- Chlorambucil: IP/PF
- Melphalan: IP/PF

Antimetabolites

- Methotrexate: IP/PF, PE, H, PEFF
- Azathioprine: IP/PF
- G-mercaptopurine: IP/PF
- Cytosine arabinoside: IP/PF, PE
- Nitrosoureas
- Carmustine: PF

Noncytotoxic Agents

- Amiodarone: IP/PF
- Carbamazepine: H, B
- Gold salts: IP/PF, H
- Nitrofurantoin: AH, PEFF, H, B, IP/PF
- Diphenylhydantoin: H
- Sulfasalazine: H, FA, BO, B
- Penicillamine: DA, AH, H, BO

AH, alveolar hemorrhage; *B,* bronchospasm; *BO,* bronchiolitis obliterans; *DA,* diffuse alveolitis; *FA,* fibrosing alveolitis; *H,* hypersensitivity lung reaction; *IP,* interstitial pneumonitis; *PE,* pulmonary edema; *PEFF,* pleural effusion; *PF,* pulmonary fibrosis.

Diagnosis/Clinical Findings

Characteristic clinical features of drug-induced pulmonary disease include fever, malaise, dyspnea, and a nonproductive cough. Initial radiographic studies may be normal but usually demonstrate a diffuse alveolar and/or interstitial involvement. Pulmonary function studies may be of either an obstructive or restrictive pattern. Hypoxemia enhanced by exercise is an early and clinically important finding because interstitial pneumonitis and pulmonary fibrosis constitute a major portion of drug-induced pulmonary disease. Histologic examination of lung tissue is frequently indicated to confirm the clinical diagnosis and to rule out other potential causes of pneumonitis such as *Pneumocystis,* viral, or fungal infections that often occur in children treated with these agents.

Other complications such as hypersensitivity lung disease, noncardiogenic pulmonary edema, bronchiolitis obliterans, alveolar hemorrhage, and pleural effusion may occur in these patients. Persistent and fatal lung dysfunction may follow drug-induced pulmonary damage. Therapy should be directed at early recognition of the problem, discontinuation of the offending agent, and supportive therapy.

Idiopathic Interstitial Lung Disease

ILD of undetermined etiology is rare in adults but is even more uncommon in children. Histologic classification of the idiopathic type of ILD can be somewhat confusing, and in past years, pediatric classification mirrored the adult classification scheme. As research progressed, some overlap was noted, but it was found that pediatric interstitial lung diseases have features that are unique to pediatrics. Usual interstitial pneumonitis has never been identified in children as the diagnostic fibroblastic foci were not found in any of the cases that had initially been labeled UIP. Other interstitial pneumonias such as desquamative interstitial pneumonitis (DIP) and lymphocytic interstitial pneumonia (LIP) are seen in children but remain quite rare and have some features that are different from their adult counterparts. DIP in children is not associated with smoking, and the histologic picture is one of macrophage being the primary inflammatory cell that fills the alveolus, although histiocytes, lymphocytes, eosinophils, and plasma cells are also present. Hyaline membrane formation is not seen in DIP, and the structural integrity of the alveolar unit is usually maintained. DIP tends to be responsive to steroids.[233] LIP is seen mostly in patients with immune deficiencies and connective tissue disorders. LIP tends to be insidious in onset and appears as a result of infiltration of the interstitium by plasma cells, mature lymphocytes, and histiocytes. Nonspecific interstitial pneumonitis histologically is a mixture of inflammation and fibrosis. This entity has been identified in children. Cryptogenic organizing pneumonia has been identified in children as an isolated phenomenon or with infection, asthma, drug reactions, malignancies undergoing chemotherapy, bone marrow transplantation, and autoimmune disorders. Prognosis is usually excellent, and patients have an excellent response to corticosteroids. Acute interstitial pneumonia is a rapidly progressive disorder with a histologic appearance consistent with the organizing form of diffuse alveolar damage. This diagnosis generally has a poor prognosis. Some interstitial lung diseases that are unique to infancy most likely in the past had been labeled under the aforementioned interstitial lung diseases but truly belong in their own classification scheme. These syndromes are persistent tachypnea of infancy (neuroendocrine cell hyperplasia of infancy), follicular bronchitis, cellular interstitial pneumonitis (pulmonary interstitial glycogenosis), chronic pneumonitis of infancy, and genetic abnormalities of surfactant function.[235] Detailed discussions of these disorders of infancy or the other interstitial lung diseases and their management are beyond the scope of this chapter but can be found in various review articles.[236-241] Patients who do not respond to medical therapy should be considered candidates for lung transplantation.

Pediatric Pulmonary Hemorrhage

Pulmonary hemorrhage (PH) is a potentially life-threatening event that can occur at any age. The clinical presentation varies from massive fatal hemoptysis to silent bleeding with respiratory distress and anemia. Rapid determination of the etiology of the PH and institution of specific therapy are often difficult. This section examines the less common causes of PH. PH resulting from trauma and infection is not discussed.

Definition

PH is defined as extravasation of blood into airways and/or lung parenchyma. Massive PH in adults is defined as blood loss of 600 mL or more in 24 hours.[242-246] In infants, Esterly and Oppenheimer[245] characterized massive PH as the involvement of at least two pulmonary lobes by confluent foci of extravasated erythrocytes. Loss of 10% of a patient's circulating blood volume into the lungs regardless of age causes a significant alteration in cardiorespiratory function and should be considered massive. The diagnosis of PH following an episode of silent bleeding is established by pulmonary hemosiderosis, which is the abnormal accumulation of iron within lung parenchyma and alveolar macrophages.

Pathophysiology

Accumulation of blood in the airways following a significant episode of PH creates multiple problems. These problems include production of a diffusion barrier resulting in hypoxemia and reduction in the diameter of involved airways, which in turn increases airway resistance and may lead to airway obstruction.

Reduction in pulmonary compliance and impairment of ventilation may occur.[246-248] These changes in respiratory function increase both the ventilatory and myocardial work necessary to maintain a normal arterial oxygen tension. Interstitial fibrosis that develops following repeated episodes of PH results in reduced carbon monoxide diffusion and diminished static and dynamic lung compliance.

Etiology

Classification of the etiologies of PH provides a simple framework to proceed with diagnostic and therapeutic interventions (Box 55.6). Diffuse PH is usually associated with less total blood loss and can occur from either immune or nonimmune mechanisms. Diffuse, immune PH typically affects adolescents and, less commonly, school-aged children. Focal PH is commonly responsible for massive PH and carries a mortality rate greater than 50%.[247,249-250] Focal PH typically affects preschool-aged children but may occur in infancy.

Box 55.6

Causes of Pulmonary Hemorrhage

Diffuse

Nonimmune

- Neonatal

- Congenital heart disease
- Hematologic

Immune

- Lower respiratory and renal
- Goodpasture syndrome
- Idiopathic rapid progressive glomerulonephritis
- Upper and lower respiratory and renal
- Wegener granulomatosis
- Multisystem organ involvement
- Systemic lupus erythematosus
- Polyarteritis nodosa
- Behçet syndrome
- Henoch-Schönlein syndrome
- Rheumatoid arthritis

Focal

- Foreign body aspiration and chronic retention
- Sequestration
- Arteriovenous fistula
- Bronchogenic and gastroenteric cysts
- Thrombus or embolus
- Neoplasms: angiomas, adenomas

Diffuse/Nonimmune Pulmonary Hemorrhage

PH in the neonate occurs in 0.7 to 4 per 1000 live births and is present in 6% to 26.3% of neonates at postmortem examination. Risk factors associated with PH in the neonate include asphyxia, infection/sepsis, CNS injury, weight less than 1500 g and/or small-for-gestational age, male sex, congenital heart disease, idiopathic respiratory distress syndrome, and coagulation disorders.[250,251] Intraalveolar hemorrhage appears to occur more commonly in neonates of older gestational age. Pulmonary hemorrhage in neonates as a primary occurrence is uncommon.[250]

Pathogenesis of PH in the neonate is considered to result from the development of persistent pulmonary hypertension with right-to-left intracardiac shunting of blood, resulting from hypoxia and acidosis. Left ventricular failure ensues, causing an increase in pulmonary capillary pressure and subsequent disruption of pulmonary capillary and alveolar membranes. Severe CNS injury may indirectly affect cardiac function, causing increased left ventricular end-diastolic pressure.[252]

Severe hemoptysis and life-threatening PH are rare in the preadolescent child with congenital heart disease. However, a drastic increase in pulmonary capillary pressure in children with pulmonary atresia, unilateral pulmonary venous atresia, total anomalous pulmonary venous drainage, mitral stenosis, cor triatriatum, or hypoplastic left heart syndrome may result in massive PH.[252,253]

Although the lungs are an infrequent site for early manifestations of primary bleeding disorders,[243,246] a coagulopathy should be ruled out during the management of any patient with PH. In patients with leukemia, PH occurs most frequently when the platelet count is lower than 10,000/mm.

Diffuse/Immune Pulmonary Hemorrhage

The classic clinical triad of hemoptysis, microcytic hypochromic anemia, and diffuse alveolar-filling opacities on a chest radiograph (Fig. 55.1) is found in most episodes of PH in this category. Although the lung may be the only organ affected, more frequently multiple organs are involved. In patients with PH, establishing which extrapulmonary organs are involved by the disease helps to narrow the differential diagnosis of which of the immune-mediated disorders is most likely present.

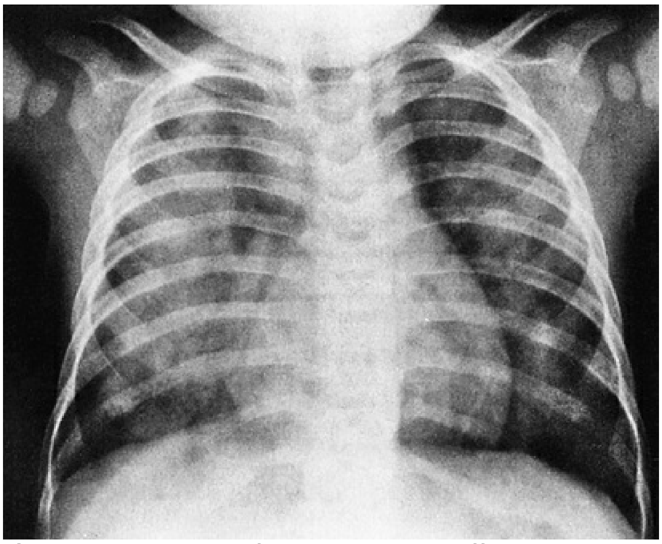

FIG. 55.1 Chest radiograph of a patient with diffuse immune pulmonary hemorrhage.

Diffuse parenchymal bleeding without evidence of extrapulmonary involvement occurs in patients with idiopathic pulmonary hemosiderosis, Heiner syndrome, and drug-induced PH. Idiopathic pulmonary hemosiderosis, a disease of childhood, is a diagnosis of exclusion. Clinically, episodes of PH recur, with 30% to 50% of patients eventually dying of exsanguination and/or respiratory failure.[254,255] Microscopic

examination of the lungs is compatible with nonspecific injury rather than a specific cause such as vasculitis or immune deposits.[254] Heiner syndrome, which affects children between the ages of 6 months and 2 years, usually manifests as other symptoms, such as chronic rhinitis, recurrent otitis media, and growth retardation.[255] Tests for precipitating antibodies to milk proteins are positive. Symptoms resolve when milk and milk products are eliminated from the diet.

Although uncommon, exposure to or inhalation of D-penicillamine, lymphangiography dye, trimellitic anhydride, cocaine, and exogenous surfactant[256,257] has been associated with development of PH. Acute PH of an undetermined etiology occurring in infants has been reported.[258,259]

Idiopathic rapidly progressive glomerulonephritis is usually a disease of older adults (mean age, 55-60 years). In children with PH and either proteinuria, hematuria, or red cell casts, Goodpasture syndrome is the most likely etiology. The presence of a linear immunofluorescent staining of Ig and C3 along glomerular capillary walls and antibasement membrane antibody (ABMA) in the serum confirms the diagnosis of Goodpasture syndrome. Renal biopsy is the preferred primary method of confirming the diagnosis because an ABMA assay is not readily available at most institutions. ABMA is a cytotoxic plasma Ig that reacts immunologically with components of alveolar and glomerular basement membrane. Stress failure of pulmonary capillaries because of alteration of the alveolar and glomerular basement membrane may contribute to the likelihood of PH in these patients.[260] Fifty percent of patients with Goodpasture syndrome die of asphyxia as a result of massive PH. The presence of sinusitis and/or bilateral, multiple cavitary pulmonary nodules and evidence of glomerulonephritis in patients with PH help distinguish Wegener granulomatosis from the other vasculitides.[261] Serositis, arthritis, facial erythema, fever, and glomerulonephritis are present before the development of PH in patients with systemic lupus erythematosus (SLE).[262] Ten percent of all cases of immune-mediated PH are associated with SLE.[262] The onset of PH in patients with SLE is abrupt. Pulmonary histology may or may not reveal a small vessel vasculitis characterized by neutrophilic infiltration of vessel walls and necrosis of capillaries and alveolar septa. Renal histology shows a vasculitis represented by focal and segmental glomerulonephritis with absent or minimal immune deposits. The majority of patients who have SLE and PH die.[262] PH has been reported with most of the vasculitides, but the incidence is much lower than in the SLE population. Constitutional signs and symptoms, such as musculoskeletal involvement, blood dyscrasias, and dermatitis, are the predominant clinical features of polyarteritis nodosa, the second most likely vasculitis-associated disease to cause PH.[263,264] A segmental necrotizing (granular pattern) vasculitis is the characteristic lesion of polyarteritis nodosa, with PH a dominant feature.[265] Recurrent uveitis, mucocutaneous ulcerations, and genital ulcerations in a patient with PH suggests Behçet syndrome as the etiology. Other clinical features seen with Behçet syndrome include arthritis, gastrointestinal disease, cardiovascular involvement, and CNS disease.[266,267] A necrotizing vasculitis of small- to medium-sized arteries and veins and thromboses of the terminal vascular beds or vena cava confirm the diagnosis.

Although PH is an extremely rare complication of Henoch-Schönlein purpura or syndrome (when abdominal pain and arthritis precede the purpura), it should be treated aggressively because it may be fatal. In a few patients with rheumatoid arthritis, syndromes resembling idiopathic pulmonary hemosiderosis without

evidence of vasculitis or renal disease have developed.

Focal Pulmonary Hemorrhage

Congenital malformations that may be responsible for PH during infancy include angiomas and bronchogenic and gastroenteric cysts.[249] Angiomas are located in the subglottic area and present with symptoms of airway obstruction by age 6 months in almost 90% of cases. Bronchogenic cysts arise from abnormal branching of the tracheobronchial tree, are lined with ciliated columnar epithelium, are filled with mucoid fluid, and if they are in communication with the airway, they may demonstrate an air-fluid level. They are prone to infection and may bleed if contiguous vessels erode. Gastroenteric cysts, which are enteric duplication cysts lined with gastric mucosa, produce acid peptic secretions that may erode through adjacent vessels to cause bleeding. Pulmonary sequestration, arteriovenous fistula, and bronchial adenomas are congenital malformations that may present in childhood or later life with PH. With its tendency to become recurrently infected, a sequestered lobe may suffer erosion into its systemic arterial supply, causing massive PH.[249] Pulmonary arteriovenous fistula with or without telangiectasia (isolated or familial) may produce massive PH during childhood, but this usually does not occur until adulthood.[265,266,268] Adenomas are highly vascular tumors that, with minor trauma or inflammation, can cause PH. Acquired causes of focal PH include aspiration of an organic foreign body and development of a pulmonary arterial thrombus or embolus.[247] A patient presenting with PH and wheezing should lead the clinician to suspect a diagnosis of foreign body aspiration. Prolonged retention of an organic foreign body leads to hyperplasia of tortuous bronchial vessels, varicosities, and bronchiectasis, any of which may cause PH. Thrombi or emboli may develop in postoperative immobile children with central venous or pulmonary catheters, in female adolescents using oral contraceptives, or in patients with homozygous deficiency of antithrombin III, protein S, and protein C. Focal PH may develop in children with cystic fibrosis as a result of bronchiectasis.

Treatment

General

The primary objectives in treatment of PH are twofold: (1) to rapidly control the bleeding to prevent tissue hypoxia and/or ischemia resulting from airway obstruction and exsanguination and (2) to stabilize hemodynamics to prevent further damage to the kidneys or other extrapulmonary organs by the underlying disorder.[244,267] Initial management of the patient with severe PH should occur in the setting of a critical care unit because of the potential lethality of this event (Box 55.7). General care measures include use of the Trendelenburg position as tolerated, oxygen supplementation, mechanical ventilation, and hemostasis therapy when indicated. The Trendelenburg position may help clots propagate superiorly and exit the airway. This position may not be well tolerated by patients with respiratory or cardiac embarrassment. Positive end-expiratory pressure during mechanical ventilation may become necessary to reverse hypoxemia and may provide a measure of tamponade to the site of hemorrhage.[244] Coagulation factors should be administered when indicated to lessen the severity of bleeding. Hemodynamic

monitoring with a pulmonary arterial catheter may be beneficial in some instances because high pulmonary artery occlusion pressure may worsen PH of any etiology. Short-term control of bleeding may be obtained with insertion, under direct vision, of a balloon-tipped (Fogarty) catheter into the affected portion of the airway. Right upper lobe bleeding is best managed by intubating the left main stem bronchus with a cuffed endotracheal tube and inflating the cuff of the tube. Utilization of a "double-lumen" or Carlens-type endotracheal tube may also be helpful in isolating the bleeding segment. However, the diameter of these tubes precludes their use in smaller children, and proper positioning may prove difficult.[244,269] Rigid bronchoscopy is the best means of identifying the source and type of bleeding, but it also has therapeutic applications.[269-271] The rigid scope readily establishes an adequate airway and can be used for large-volume isotonic saline solution lavage and for suctioning large volumes of blood. Fiberoptic bronchoscopy should be reserved for diagnostic purposes, including definitive identification of the bronchopulmonary segments involved and BAL. BAL provides useful information by permitting culture of the lavage for bacteria, fungi, mycobacteria, and viruses and quantitative assessment of the hemosiderin content of the alveolar lavage. Interpreting the presence or absence of hemosiderin-laden macrophages should be done cautiously because macrophages may not appear for up to 48 hours following an acute episode of bleeding and usually disappear by 2 weeks.

Box 55.7

Treatment of Pulmonary Hemorrhage

General

- Admission to pediatric ICU
- Positioning (intermittent Trendelenburg)
- Oxygen supplementation
- Mechanical ventilation (positive end-expiratory pressure)
- Hemodynamic monitoring
- Hemostasis replacement therapy
- Endobronchial tamponade (Fogarty catheter, cuffed endotracheal tube)

Specific

Immune

- Corticosteroids
- Other immunosuppressive agents (azathioprine, cyclophosphamide)
- Plasmapheresis (Goodpasture syndrome)

- Bilateral nephrectomy
- Deferoxamine, milk-free diet

Focal

- Surgical resection
- Selective embolization of bronchial vessels

Specific

Despite the different etiologies in the category of immune-mediated PH, the response to corticosteroid therapy is swift (within 24-48 hours) as assessed by transfusion requirements, hemoglobin concentration, hemoptysis, and absence of new infiltrates.[255] Although controlled clinical trials have not been performed to validate this temporal relationship suggestive of therapeutic benefit, the risk of administering a short course of high-dose corticosteroids in this setting is low. Hence, the corticosteroids adrenocorticotropic hormone (10–25 units/day), methylprednisolone (2–4 mg/kg/day), or hydrocortisone (4 mg/kg/day) should be administered early in a patient with an acute, life-threatening episode of immune-mediated PH. Once remission is achieved, corticosteroids should be tapered until they are discontinued or symptoms recur. In cases of inadequate response to corticosteroids alone, other immunosuppressive agents (eg, azathioprine, cyclophosphamide, chlorambucil) have been administered with some success in persons with the immune-mediated PH syndromes.[272] Azathioprine (1.2–5 mg/kg/day) with prednisone (5–20 mg every 6 hours) is a typical treatment combination. Cyclophosphamide is the drug of choice for treatment of patients with Wegener granulomatosis.[273] Once a specific diagnosis is made for the various etiologies of immune-mediated PH, directed therapies are available, including immunosuppression and plasmapheresis. These therapies are beyond the scope of this chapter and are discussed in the literature.[273-275] Administration of IV vasopressin to a patient with massive hemoptysis may temporarily control the bleeding. Surgical resection of a bleeding focus remains the procedure of choice if feasible. Severe bleeding at the time of resection resulting in single lung ventilation increased the mortality rate from 12% to 25% in one series. Pulmonary embolectomy should be considered for patients with an acute large embolus, especially if fibrinolysis is contraindicated.[246,276,277] For focal PH resulting from increased bronchial circulation, selective embolization or occlusion of bronchial vessels with glass microspheres, small pledgets of absorbable gelatin sponge or polyvinyl alcohol sponge may provide temporary hemostasis. Embolization should be considered in the unstable or poor surgical candidate with focal PH. Complications of embolization include inadvertent CNS or coronary artery occlusion and transverse myelitis with resulting paraplegia.

Summary

PH that does not occur in the familiar setting of trauma or infection can be classified according to extent of pulmonary involvement (ie, diffuse or focal). PH occurs most

commonly during the neonatal period as a result of diffuse nonimmune mechanisms. PH in the neonate is a preterminal complication of severe disorders of the cardiovascular and respiratory systems. The best initial approach to diagnosis and specific therapy in the older child is determining the extent of extrapulmonary organ involvement. Diseases that lead to focal hemorrhage are more likely to cause massive hemoptysis, typically affect younger children, and may be amenable to surgical resection. If the suspected cause of PH is a diffuse, immune-mediated process, a trial of corticosteroids should be administered early because of the rapid, dramatic response seen in patients with some disorders. A systematic approach to diagnosis in persons with PH will improve the odds of a favorable outcome for patients with this rare phenomenon.[246,270]

CHAPTER 56

Diseases of Pulmonary Circulation

Satyan Lakshminrusimha, Vasanth H. Kumar

PEARLS

- A normal fetus is in a state of physiologic pulmonary hypertension and is dependent on the placenta for gas exchange.
- The onset of breathing and lung inflation at birth and the resultant increase in oxygen tension decrease pulmonary vascular resistance (PVR), which is essential for establishing a normal postnatal circulatory pattern.
- Elevated pulmonary vascular resistance relative to systemic vascular resistance, which may result from either vasoconstriction or structural remodeling of the pulmonary vasculature, characterizes persistent pulmonary hypertension of the newborn (PPHN).
- An increase in pulmonary vascular smooth muscle can occur in utero or after birth and result in peripheral extension of the smooth muscle onto vessels that do not normally have muscle layers. This process may contribute to the pathology of PPHN.
- The gold standard in defining PPHN rests on the echocardiographic findings of right-to-left shunting of blood at the foramen ovale and/or ductus arteriosus, as well as evidence of elevated pulmonary arterial pressure in the absence of structural heart disease.
- High-frequency oscillatory ventilation, surfactant therapy, and nitric oxide have decreased the need for extracorporeal membrane oxygenation in infants with PPHN.
- In children, it is important to establish an accurate diagnosis with respect to etiology because therapy may depend on the etiology of pulmonary hypertension.
- Echocardiography is a useful screening tool in children with suspected pulmonary arterial hypertension (PAH). Before committing to therapy specific to childhood PAH, diagnosis needs to be confirmed by catheterization.
- Calcium channel blockers are useful only for patients who respond to vasodilator testing during cardiac catheterization.
- Overall exercise capacity, symptoms as assessed by World Health Organization

classification, and hemodynamic parameters of right ventricular function help not only in the management of these patients but also correlate well with survival.
- Recent advances in the medical management of PAH have widened the spectrum of therapeutic modalities available for children to include prostanoids, oral endothelin receptor antagonists, PDE5 inhibitors, and some forms of combination therapies.
- Aggressive medical therapy combined with prompt and meticulous follow-up will improve quality of life and survival of children with pulmonary hypertension. Early referral to expert centers is crucial to patient survival.

Etiology and Treatment of Pulmonary Hypertension

This chapter addresses the neonatal and pediatric aspects of pulmonary hypertension (PH). First, unique aspects of fetal and postnatal development of pulmonary vasculature, transitional circulation, and developmental regulation of pulmonary vascular tone are briefly discussed. This background helps in understanding the pathophysiology and treatment of pulmonary vascular disorders in newborns and children.

Developmental Pulmonary Vascular Anatomy

The vascular network of the developing endodermal pair of lung buds is derived from the surrounding mesenchyme of the splanchnic mesoderm beginning at 4 weeks of gestation. These vessels accompany the developing airways, differentiate into arteries, and join the larger pulmonary arteries that originate from the sixth aortic arch. The veins arise separately within the loose mesenchyme of the lung septa and subsequently connect to the developing left atrium.

In the normal fetal lung, fully muscularized thick-walled preacinar arteries extend to the level of terminal bronchioles, whereas the intraacinar arteries (ie, those accompanying respiratory bronchioles) are partially muscular (surrounded by a spiral of muscle) or nonmuscular. Arteries at alveolar ducts and alveolar walls are nonmuscular.[1] An increase in intrauterine vascular smooth muscle, resulting from peripheral extension of smooth muscle into vessels that do not normally contain muscle layers, may contribute to the pathophysiology of persistent pulmonary hypertension of the newborn (PPHN).[2] Increased muscularization of the pulmonary arteries has been described in infants with severe meconium aspiration syndrome (MAS) with PPHN.[3] Neonates who die of PPHN may have a striking distal extension of smooth muscle in the intraacinar region, thickening of the media and adventitia, and excessive accumulation of the matrix protein in the pulmonary vessels.[4] The increase in vascular smooth muscle and its peripheral extension can occur either prenatally or postnatally. In utero ductal ligation 1 to 2 weeks before delivery results in severe PPHN at birth associated with distal extension of vascular smooth muscle in newborn lambs[5] similar to the changes seen in human infants dying with severe PPHN.

Developmental Pulmonary Vascular Physiology

The normal fetus is in a state of physiologic pulmonary hypertension. Most of the right ventricular output crosses the ductus arteriosus to the aorta (≈8%-10% of combined ventricular output in an ovine fetus and 13%-21% in human fetuses).[6-8] The ratio of blood entering the pulmonary arteries to the ductus arteriosus is determined by the fetal pulmonary vascular resistance (PVR) and can vary with fetal oxygenation status and gestation.[9,10]

The lung increases in weight by 6-fold from midgestation to term and the number of pulmonary vessels increases more than 10-fold.[11,12] Thus the tremendous increase in cross-sectional area of pulmonary vasculature permits pulmonary blood flow (Q_p) to increase throughout gestation. However, Q_p remains relatively constant when corrected for wet lung weight with advancing gestation.[13] A gradual increase in pulmonary arterial pressure (PAP), accompanied by a relatively constant flow per unit lung tissue, results in increasing fetal pulmonary vascular resistance (PVR) with advancing gestation.[13] A major part of this increase comes from elevated pulmonary vascular tone associated with low PO_2 in the fetal lung.[14,15] Maintaining high PVR in utero is important because the function of gas exchange is performed by the placenta, not by the lungs.

Regulation of Pulmonary Vascular Tone in Utero

Low oxygen tension and various mediators play a crucial role in maintaining elevated fetal PVR.[16] Vasoconstriction in response to low oxygen tension contributes to high PVR in the fetal lamb as it approaches term.[13-15] Arachidonic acid metabolites such as prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) and thromboxane A_2 (TXA_2) are synthesized by the fetal lung via the cyclooxygenase pathway[17] and are pulmonary vasoconstrictors in the fetal and newborn lungs. Blocking prostaglandin or thromboxane synthesis does not decrease fetal PVR but prevents the decrease in PVR in response to rhythmic distention of the lung in fetal lambs.[18] Serotonin increases fetal PVR.[19,20] The use of selective serotonin reuptake inhibitors (SSRIs) during the last half of pregnancy has been associated with an increased incidence of PPHN in at least three human population studies.[21-24] While the mechanism by which SSRIs induce pulmonary hypertension in newborn is not known, it is speculated that higher drug-induced serotonin levels result in pulmonary vasoconstriction. However, recent studies have questioned the association between maternal SSRI intake and PPHN.[25,26] Furthermore, the severity of PPHN following fetal exposure to SSRI has not been well described and a recent report observed no differences in right pulmonary artery Doppler pulsatility index (PI) in fetuses of mothers exposed to SSRI antidepressants.[27]

Endothelins (ETs) are 21-residue peptides[28,29] whose role in regulating vascular tone and vasomotor responses has been studied intensively in the past decade. Three distinct ET isoforms have been described: endothelin-1 (ET-1), endothelin-2 (ET-2), and endothelin-3 (ET-3), cleaved from ET precursors big ET-1, big ET-2, and big ET-3, respectively, by an ET-converting enzyme. Endothelin-1 synthesized by vascular endothelial cells is a potent vasoconstrictor.[30] Infusion of big ET-1, the precursor of ET-1, into fetal lambs causes sustained pulmonary vasoconstriction.[31] Currently at least two receptor subtypes, ET_A and ET_B, are thought to mediate responses to ETs

(Fig. 56.1). The ET_B receptor plays a role in vasodilation and ET_A receptor in vasoconstriction. Selective blockade of the ET_A receptor causes fetal pulmonary vasodilation.[32-34] Some investigators suggest a significant role for an endothelial ET_B receptor in vasodilation and a smooth muscle ET_B receptor and ET_A receptor in vasoconstriction.[35,36] Vasoconstriction induced by ET-1 is mediated by calcium,[37] whereas the vasodilator properties are mediated by endothelium-derived nitric oxide (NO).[36,38] ET-1 may play a role in the change that occurs in the pulmonary vasculature at birth. It is possible that prenatally endogenous ET-1 primarily stimulates ET_A receptors to cause vasoconstriction and that ET_B receptors are less active in fetal life.[32] However, ET_B receptors mediate the vasodilator responses to ET-1 in the fetus, and there is a suggestion that abundance of ET_B receptors may be of physiologic importance in decreasing PVR at birth.[39]

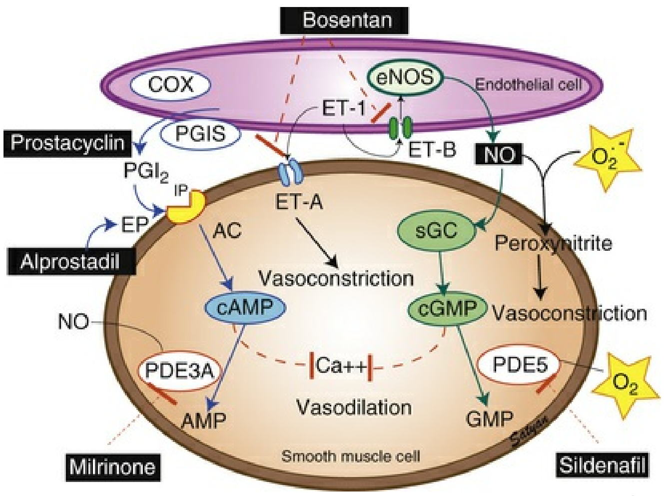

FIG. 56.1 Endothelium-derived vasodilators—prostacyclin (PGI_2), nitric oxide (NO), and vasoconstrictor (endothelin, ET-1). Cyclooxygenase (COX) and prostacyclin synthase (PGIS) are involved in the production of prostacyclin. Prostacyclin acts on its receptor (IP) in the smooth muscle cell and stimulates adenylate cyclase (AC) to produce cyclic adenosine monophosphate (cAMP). Cyclic AMP is broken down by phosphodiesterase 3A (PDE 3A, the enzyme most prevalent in vasculature) in the smooth muscle cell. Milrinone inhibits PDE 3A and increases cAMP levels in arterial smooth muscle cells and cardiac myocytes resulting in pulmonary (and systemic) vasodilation and inotropy. Nitric oxide (NO) stimulates PDE 3A.[362,363] Endothelin is a powerful vasoconstrictor and acts on ET-A receptors in the smooth muscle cell and increases ionic calcium concentration. A second endothelin receptor (ET-B) on the endothelial cell stimulates NO release and vasodilation. Endothelial nitric oxide synthase (eNOS) produces NO, which diffuses from the endothelium to the smooth muscle cell and stimulates soluble guanylate cyclase (sGC) enzyme to produce cyclic guanosine monophosphate (cGMP). Cyclic GMP is broken down by PDE5 enzyme in the smooth muscle cell. Sildenafil inhibits PDE5 and increases cGMP levels in pulmonary arterial smooth muscle cells. Natriuretic peptides stimulate particulate guanylate cyclase (pGC) to produce cGMP. Cyclic AMP and cGMP reduce cytosolic ionic calcium concentrations and induce smooth muscle cell relaxation and pulmonary vasodilation. Nitric oxide is

a free radical and can avidly combine with superoxide anions to form a toxic vasoconstrictor, peroxynitrite. Hence the bioavailability of NO in a tissue is determined by the local concentration of superoxide anions. Hyperoxic ventilation with 100% oxygen can increase the risk of formation of superoxide anions in the pulmonary arterial smooth muscle cells and limit the bioavailability of NO and stimulate PDE5 activity.[138] Medications used in persistent pulmonary hypertension are shown in black boxes. (Copyright Satyan Lakshminrusimha.)

Transitional Circulation

Successful transition is accomplished when the fluid-filled fetal lungs are distended with air during breathing[16] leading to a rapid decrease in PVR.[40] This leads to an eightfold increase in Q_p and increased left atrial pressure above right atrial pressure, closing the foramen ovale. SVR increases at birth, in part because of removal of the low resistance bed of the placenta. As PVR becomes less than systemic, flow across the ductus reverses. Within the first 5 minutes after birth, oxygen-induced vasodilation and lung expansion decrease PVR to approximately half of systemic resistance. Over the first few hours after birth, the ductus arteriosus closes, largely in response to the increase in oxygen tension. At this point the normal postnatal circulatory pattern is established.

Further reduction of PVR occurs over the first few weeks of postnatal age and is accompanied by rapid structural remodeling of the entire pulmonary bed from the main pulmonary arteries to the capillaries.[41] During this remodeling, changes in the shape and geometric orientation of endothelial and smooth muscle cells cause luminal enlargement. Maturation of smooth muscle function, thinning of endothelial cells, and more gradual changes in elastic and connective tissue occur over the next few weeks.

Factors Responsible for Decrease in Pulmonary Vascular Resistance at Birth

The onset of ventilation with rhythmic inflation of the lungs at birth with a resultant increase in oxygen tension in the lungs leads to a decrease in PVR. Each of these stimuli has been shown to decrease vascular resistance and increase blood flow in the lungs of fetal lambs.[13,16,40,42]

The drop in PVR soon after birth is accompanied by production of prostacyclin (PGI_2) and nitric oxide (NO). PGI_2 synthesized by endothelial cells appears to relax smooth muscle by producing cyclic adenosine monophosphate (cAMP). Even though blockade of prostaglandin synthesis, by either indomethacin[43,44] or meclofenamate,[18] blunts the decrease in PVR, it does not completely disrupt the transition to gas exchange. In addition cyclooxygenase through the PGE_2 pathway plays an important role in maintaining patency of the ductus arteriosus. PPHN has been observed in infants of mothers receiving aspirin or nonsteroidal antiinflammatory drugs that inhibit cyclooxygenase activity,[45] although this association has been recently called into question.[46]

Acetylcholine,[47] bradykinin,[48] and histamine[49] are fetal pulmonary vasodilators,

which in many species act by an endothelium-dependent mechanism (Fig. 56.1). They stimulate the production of NO by vascular endothelium. NO activates soluble guanylate cyclase (sGC) to produce the second messenger cyclic guanosine monophosphate (cGMP). cGMP induces relaxation of vascular smooth muscle through activation of a cGMP-dependent protein kinase that produces a lowering of cytosolic ionic calcium, in part through activation of potassium channels.[50,51] There is strong evidence that NO is an important mediator of the decrease in PVR at birth.[52] The dilation of the fetal pulmonary circulation caused by an increase in oxygen tension is mediated in large part by endogenous synthesis of NO.[53] Prolonged administration of nitric oxide synthase (NOS) inhibitors in late-gestation lambs to block endogenous NO synthesis does not affect basal PVR but markedly blunts the decrease in PVR observed at birth.[54]

Evidence suggests that many other mediators can act as pulmonary vasodilators during fetal life and at birth. The purines adenosine triphosphate (ATP) and adenosine[10,55-58]; natriuretic peptides such as atrial natriuretic peptide (ANP), B-type natriuretic peptide (BNP), and C-type natriuretic peptide (CNP)[59]; and arachidonic acid metabolites such as EETs, generated through the cytochrome P-450 pathway, are potent pulmonary vasodilators.[60] As pulmonary vasodilation at birth is a vital step in establishing postnatal life, it is logical that there would be sufficient redundant vasodilators to compensate for failure or inadequacy of any single pathway.[61]

Persistent Pulmonary Hypertension of the Newborn

PPHN is a serious clinical condition that can result from diverse etiologies and is characterized by failure of the pulmonary circulation to adapt to extrauterine life. Elevated pulmonary-to-systemic vascular-resistance ratio (PVR/SVR) resulting from either vasoconstriction, structural remodeling of the pulmonary vasculature, intravascular obstruction, or lung hypoplasia (Fig. 56.2) characterizes PPHN. This leads to right-to-left shunting of blood across the foramen ovale and ductus arteriosus, resulting in hypoxemia. Numerous disease states with diverse etiologies can result in a similar final pathophysiology. About 10% of cases with PPHN are idiopathic, with no associated pulmonary airspace pathology. However, PPHN is usually associated with other acute respiratory conditions, such as meconium aspiration syndrome (MAS), respiratory distress syndrome (RDS), pneumonia, or congenital diaphragmatic hernia (CDH) (Fig. 56.3). Hypoxemia in these conditions can be due to ventilation/perfusion (V/Q) mismatch and intrapulmonary, as well as extrapulmonary, right-to-left shunting of blood. In some newborns with hypoxic respiratory failure, a single mechanism predominates (eg, extrapulmonary right-to-left shunting in idiopathic PPHN). However, more commonly, several of these mechanisms contribute to hypoxemia. In MAS, obstruction of the airways by meconium results in decreasing V/Q ratios and increasing intrapulmonary right-to-left shunt. Other segments of the lungs may be overventilated relative to perfusion, causing increased physiologic dead space. The same patient may also have severe PPHN with extrapulmonary right-to-left shunting at the ductus arteriosus and foramen ovale. The PPHN in MAS may result from alveolar hypoxia, inflammatory

mediators, or abnormal pulmonary vascular muscularization (Fig. 56.4).

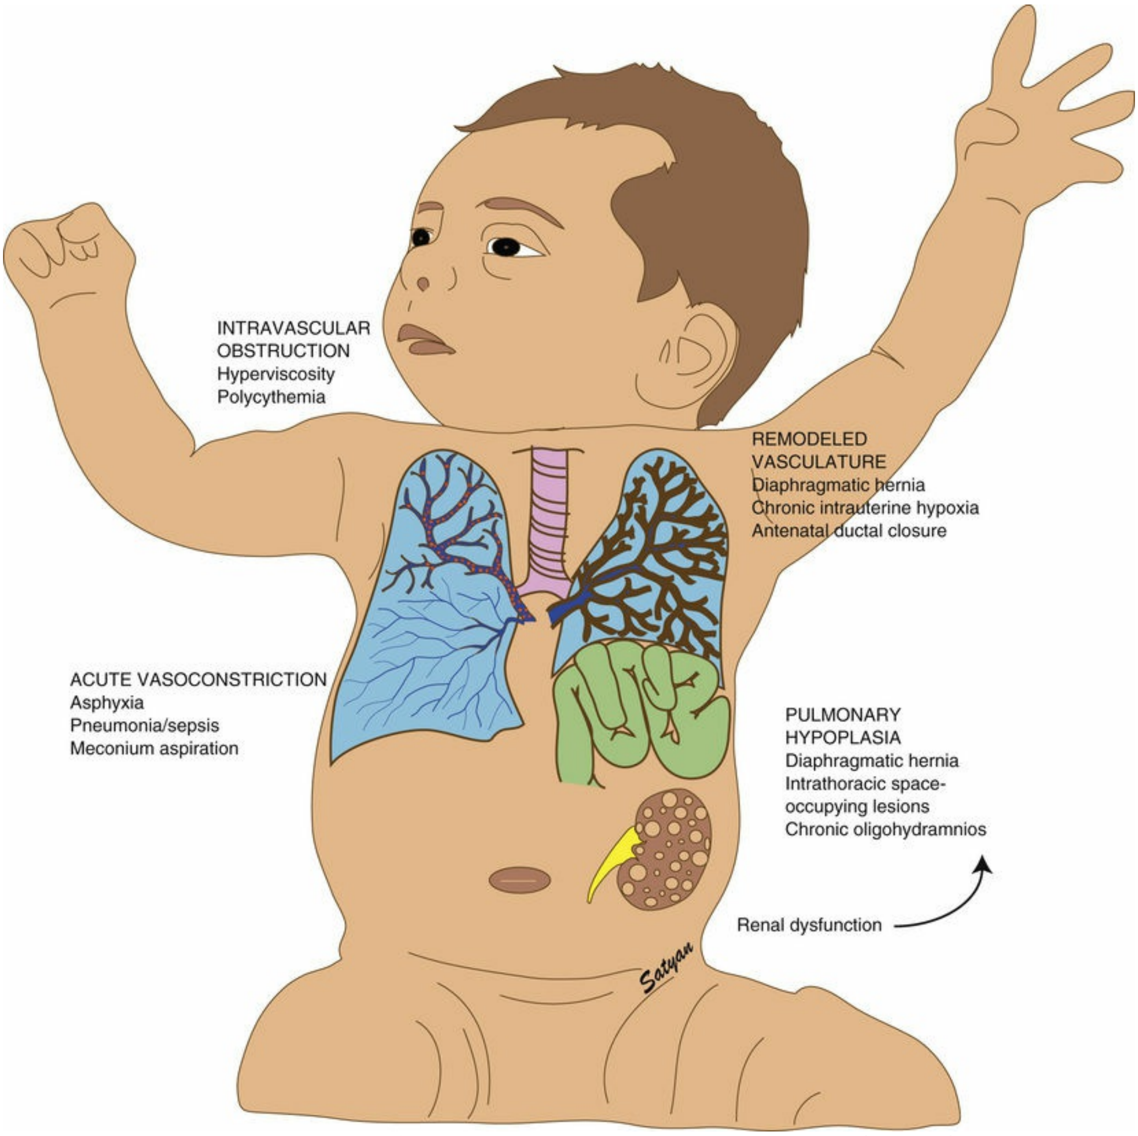

FIG. 56.2 Mechanisms of persistent pulmonary hypertension (PPHN)—Elevated pulmonary vascular resistance (PVR) is typically secondary to four mechanisms. Parenchymal lung disease (such as hyaline membrane disease [HMD]) resulting in acute alveolar hypoxia leads to pulmonary vasoconstriction. Intravascular obstruction secondary to hyperviscosity often due to polycythemia can lead to PPHN. Remodeled vasculature (maladaptation of pulmonary circulation) due to congenital diaphragmatic hernia, intrauterine closure of ductus arteriosus, and chronic intrauterine hypoxia leads to PPHN. Pulmonary hypoplasia secondary to intrathoracic space-occupying lesions such as congenital pulmonary malformations, diaphragmatic hernia, and oligohydramnios due to renal disease or chronic leakage leads to PPHN. Finally, infants born with malformations of alveolar and vascular development such as alveolar capillary dysplasia (ACD) with malalignment of pulmonary veins (MPV) have intractable and often lethal PPHN. (Copyright Satyan Lakshminrusimha.)

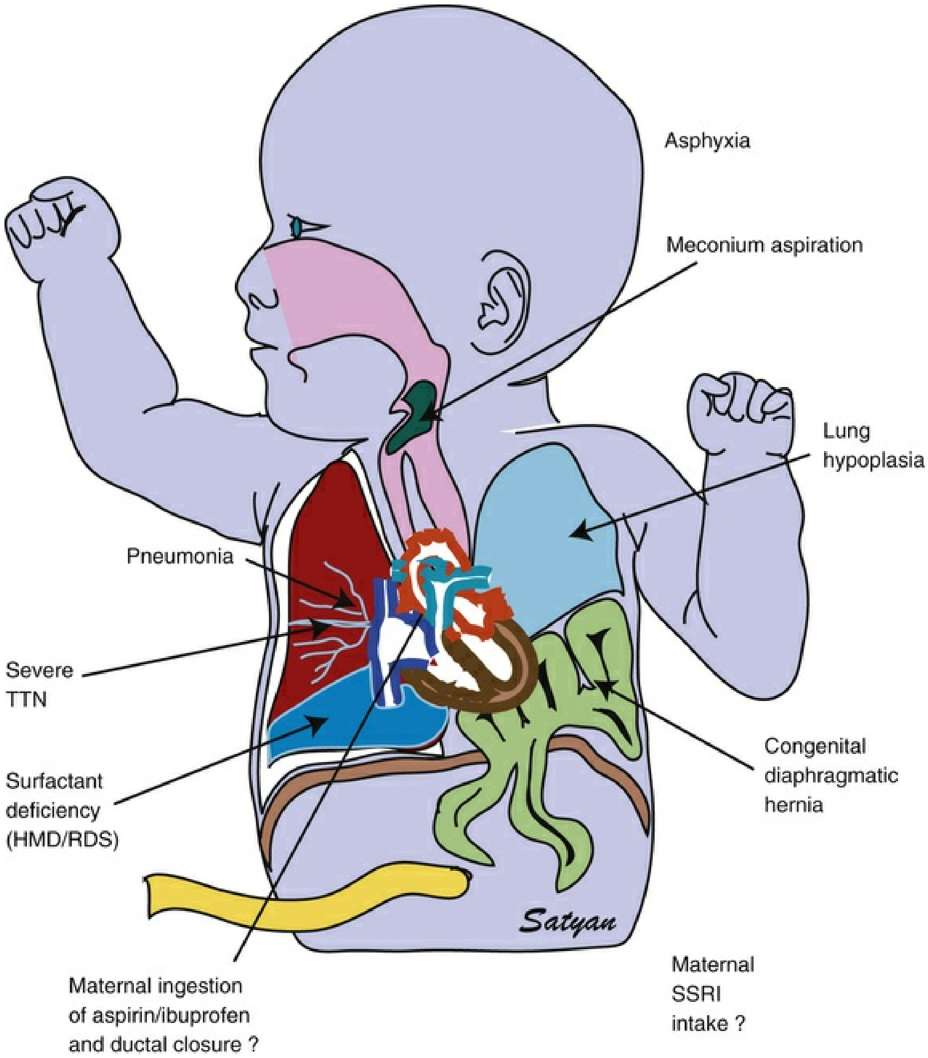

FIG. 56.3 Etiology of persistent pulmonary hypertension (PPHN)—clinically common conditions associated with PPHN (see text for details; the ? sign indicates that the association between PPHN and these conditions may be controversial).

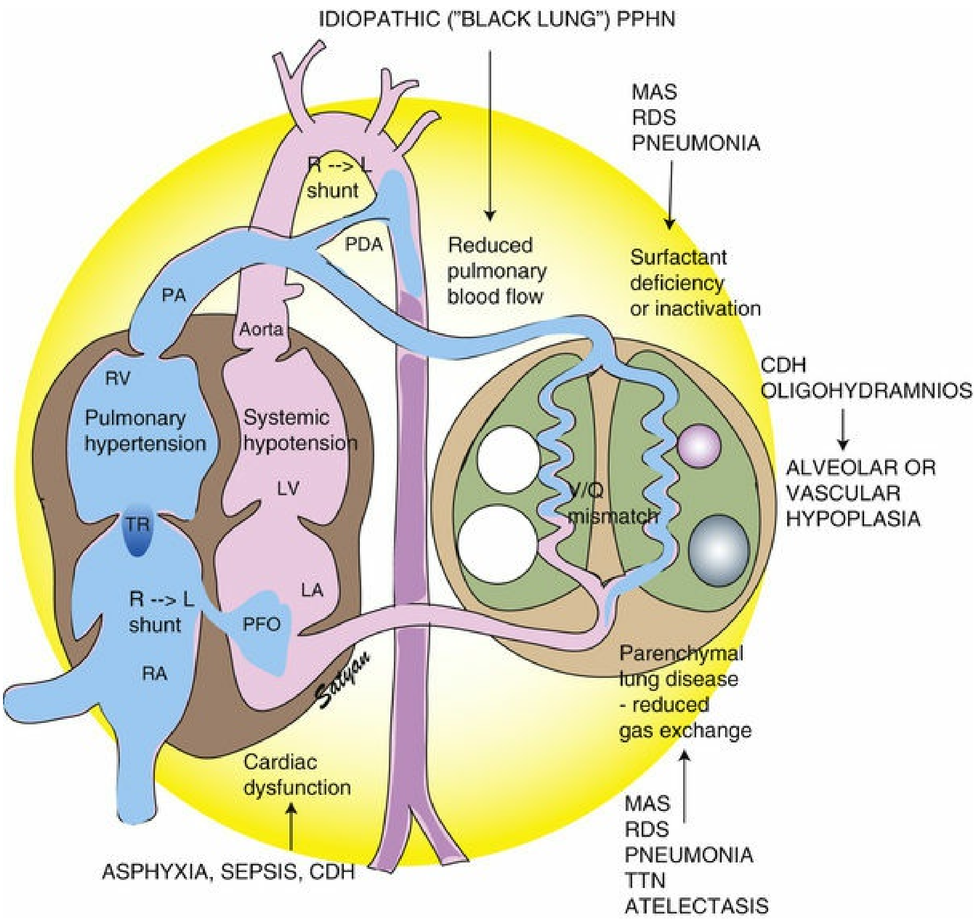

FIG. 56.4 Various etiologic factors causing persistent pulmonary hypertension (PPHN) and hemodynamic changes in PPHN/HRF. *CDH,* congenital diaphragmatic hernia; *HRF,* hypoxemic respiratory failure; *LA,* left atrium; *LV,* left ventricle; *MAS,* meconium aspiration syndrome; *PA,* pulmonary artery; *PDA,* patent ductus arteriosus; *PFO,* patent foramen ovale; *RA,* right atrium; *RDS,* respiratory distress syndrome; *RV,* right ventricle; *TTN*, transient tachypnea of the newborn; *TR,* tricuspid regurgitation. (Copyright Satyan Lakshminrusimha.)

Clinical Presentation

PPHN must be included in the differential diagnosis of hypoxic respiratory failure in term or preterm infants. Prenatal and perinatal history may provide clues to the etiology of PPHN. These include the presence of meconium, acidosis, and asphyxia at delivery and maternal risk factors for infection such as prolonged rupture of membranes, maternal fever, or positive group B *Streptococcus* status. Postmaturity also appears to be a risk factor.

Although PPHN is traditionally considered a disease of term and late-preterm infants, it is increasingly being diagnosed in extremely preterm infants.[62,63] Pulmonary hypertension in preterm infants has a bimodal postnatal age of presentation. Some preterm infants with RDS present with PPHN in the first few days of life[62] while preterm infants with bronchopulmonary dysplasia (BPD) may be diagnosed with pulmonary hypertension later in the hospital course[64] or after discharge from the neonatal ICU or during a subsequent admission to the pediatric

ICU with an intercurrent illness. Preterm infants with fetal growth restriction and born after prolonged rupture of membranes are at higher risk for developing pulmonary hypertension.[65] Pulmonary vascular disease significantly increases morbidity and mortality in BPD.[66]

Labile hypoxemia is the hallmark of PPHN (Fig. 56.5). A newborn infant who is extremely labile, with frequent desaturation episodes and wide swings in arterial Po_2, without changes in ventilator settings, should suggest the possibility of PPHN. Lability can also occur in the face of significant parenchymal disease when V/Q mismatch is severe. Auscultation of the heart in babies with PPHN may reveal a single S_2, which can be loud, and a systolic murmur of tricuspid regurgitation. Chest x-ray findings may vary depending on the etiology of PPHN. Hypoxemia out of proportion to the degree of parenchymal disease severity on chest radiography should suggest PPHN. Measurement of preductal (from right upper limb) and postductal arterial oxygenation (any lower limb) can confirm PPHN. A difference in arterial Po_2 ≥10 to 20 mm Hg or oxygen saturation ≥5% to 10% should be considered significant. Absence of a difference in oxygen tension does not exclude PPHN because shunting at the atrial level produces no ductal gradient and is probably the most common site of shunting. Thus in clinical practice, the gold standard in defining PPHN rests on the echocardiographic findings of right-to-left shunting of blood at the foramen ovale and/or the ductus arteriosus, as well as estimates of PAP. Doppler measurements of atrial and ductal level shunts provide essential information when managing a newborn with hypoxic respiratory failure. For example, left-to-right shunting at the foramen ovale and ductus arteriosus with marked hypoxemia suggests predominant intrapulmonary shunting, and interventions should be directed at optimizing lung inflation. Similarly, presence of right-to-left shunting at the ductal level and left-to-right shunting at the atrial level suggests PPHN with left ventricular dysfunction with some pulmonary venous hypertension (Table 56.1). This finding may be associated with CDH,[67] asphyxia, or sepsis.[68]

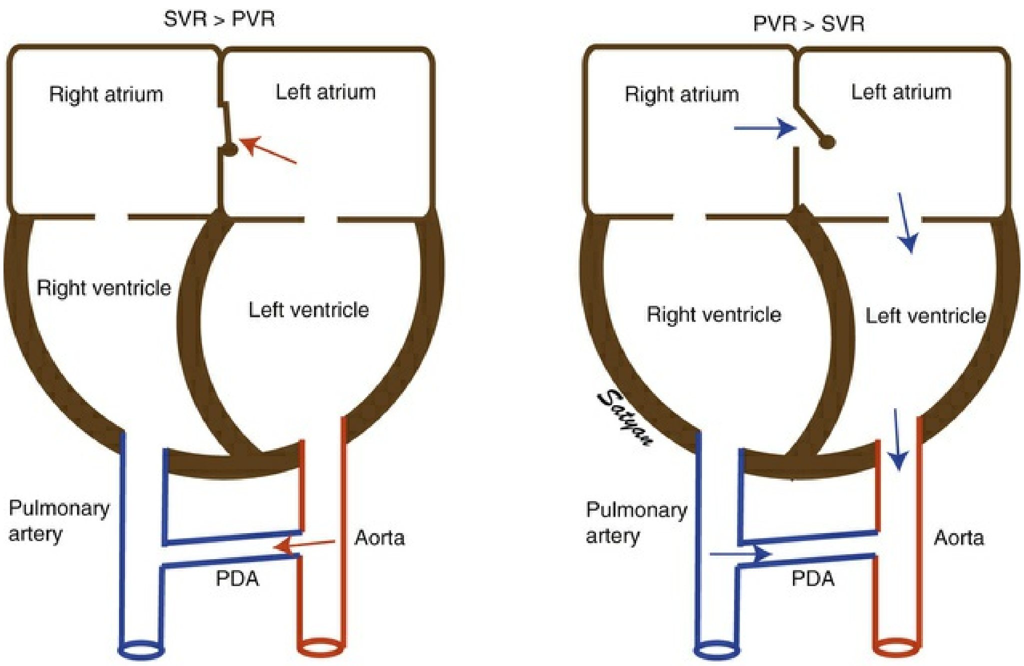

FIG. 56.5 Physiology of labile oxygenation in persistent pulmonary hypertension. When systemic vascular resistance (SVR) is higher than pulmonary vascular resistance (PVR), there is no right-to-left shunt. When PVR is close to or exceeds SVR, variable right-to-left shunt at foramen ovale and ductal levels results in labile hypoxemia. (Copyright Satyan Lakshminrusimha.)

TABLE 56.1

Differential Diagnosis of Hypoxemia in Neonate Based on Direction of Shunt at Atrial and Ductal Level on Echocardiography

Ductal Shunt	Atrial Shunt	Diagnosis	Management
R → L	R → L	PPHN	Oxygenation and inhaled NO
L → R	L → R	Parenchymal lung disease and V/Q mismatch	Lung recruitment, specific therapy NO may be beneficial
R → L	L → R	LV dysfunction (common in CDH)[67]	Milrinone
L → R	R → L	Tricuspid atresia/stenosis or pulmonic atresia/stenosis	PGE1 + Surgery
R → L (Large PA)	R → L (small LA and *no tricuspid regurgitation*)[69]	TAPVR	Surgery

CDH, congenital diaphragmatic hernia; *LV,* left ventricular; *NO,* nitric oxide; *PPHN,* persistent pulmonary hypertension; *TAPVR,* total anomalous pulmonary venous return.

Data from Kinsella JP, Ivy DD, Abman SH. Pulmonary vasodilator therapy in congenital diaphragmatic hernia: acute, late, and chronic pulmonary hypertension. Semin Perinatol. 2005;29:123-128; and Lakshminrusimha S, Wynn RJ, Youssfi M, et al. Use of CT angiography in the diagnosis of total anomalous venous return. J Perinatol. 2009;29:458-461.

Hyperoxia test (obtaining an arterial gas after 15 minutes of exposure to 100% oxygen) and/or hyperoxia-hyperventilation (hyperoxia and alkalosis to induce pulmonary vasodilation and improve PaO_2) is no longer widely practiced due to the known adverse effects of hyperoxia and alkalosis. PPHN can alternatively be confirmed by demonstrating elevated pulmonary pressures by an early

echocardiogram, when available.

B-type natriuretic peptide (BNP) concentrations in plasma correspond well with echocardiographic findings of ventricular strain.[70] Reynolds et al.[71] suggested BNP as an early indicator of PPHN in the presence of respiratory illness in neonates without CHD. BNP has been proposed as a biomarker in PPHN, especially to assess efficacy of treatment and to predict rebound PPHN.[71,72] However, its value in the practical management of PPHN is presently unclear. Some centers obtain serial (monthly) echocardiograms with BNP levels to screen for pulmonary hypertension associated with BPD in preterm infants.

Severity of PPHN

In the PICU, severity of respiratory failure is often assessed by P/F ratio (PaO_2/F_{IO2}). Severity of PPHN is commonly assessed by oxygenation index (OI) and alveolar-arterial oxygen difference ($AaDO_2$). OI is more commonly used during medical management of PPHN because it takes ventilator support into consideration and is calculated as:

$$OI = MAP \times F_{IO_2} \times 100/PaO_2$$

where *MAP* is the mean airway pressure in cm H_2O, F_{IO2} is the fraction of inspired oxygen, and PaO_2 is partial pressure of oxygen in arterial blood (in mm Hg). Hypoxemic respiratory failure can be classified into mild (OI ≤15), moderate (OI >15 to 25), severe (OI 25-40), and very severe (OI >40).[73] Disadvantages of OI include (1) it can be manipulated by changing F_{IO2} or MAP or based on the type of ventilator; (2) it requires arterial access; (3) the value may vary on the basis of the site of arterial access—right radial (preductal) versus umbilical or posterior tibial (postductal). More recently, oxygen saturation index (OSI = MAP × FiO_2 × 100/Preductal SpO_2) has been used in patients without arterial access.[74] If preductal SpO_2 is in the 70% to 99% range, OSI corresponds to approximately half of OI (OSI of 8 = OI of 16).[75] More research evaluating the clinical role for this noninvasive index is needed before its widespread use.

$AaDO_2$ is the difference between alveolar partial pressure of oxygen and arterial partial pressure of oxygen and is calculated using the following formula:

$$AaDO_2 = (Patm - P_{H_2O}) \times FiO_2 - PaO_2 - PaCO_2/RQ$$

where *Patm* is the atmospheric pressure, which is usually equal to 760 mm Hg at sea level but needs to be adjusted in high altitude. P_{H_2O} is the pressure of water vapor in one ATM, which is usually considered to be 47 mm Hg. RQ is the respiratory quotient and equal to 1 if the energy source is purely carbohydrate or equal to 0.8 when the nutritional source is a combination of carbohydrate, protein, and lipid. The disadvantage of $AaDO_2$ is that it does not take ventilator pressure into account but is useful in patients on noninvasive supplemental oxygen (eg, oxygen hood, mask, cannula).

Treatment

General Measures

Understanding the dynamic pathophysiology underlying right-to-left shunting is important to the successful management of PPHN. Infants with PPHN require supportive care tailored to the degree of hypoxemia and physiologic instability. PPHN is often associated with underlying parenchymal lung disease or systemic illness; therapy should target the underlying disease (such as antibiotics for sepsis).

Sedation

In PPHN, even mild stress can cause Po_2 to plummet within minutes. Accordingly, neonates and children with PPHN are often sensitive to activity and agitation. Minimal stimulation and sedation with narcotics such as fentanyl and morphine are commonly used to achieve this goal. Systemic hypotension due to excessive narcotic use should be avoided as it can worsen right-to-left shunts. Paralysis should be avoided, if possible, as it is associated with increased mortality.[76]

Systemic Blood Pressure Management

The lability in Pao_2 may result from the fact that when pulmonary and systemic arterial pressures are similar, small alterations in the ratio of the two can produce large changes in extrapulmonary shunting (Fig. 56.5).[77] Systemic blood pressures should be maintained at a normal range for age and gestation, as an increased systemic resistance may decrease the degree of right-to-left shunting.

The cause of systemic hypotension should be addressed first—administration of volume bolus in hypovolemia, decrease in MAP in the presence of hyperinflation, and antibiotics for sepsis. The use of dopamine to increase systemic blood pressure to reduce right-to-left shunt is a common practice. Such a practice is effective in the presence of systemic hypotension. However, increasing systemic pressure to supraphysiologic levels is not recommended.[68] In some patients with PPHN, the presence of a patent ductus arteriosus acts as a pop-off valve, limiting right ventricular preload and dysfunction. Increasing systemic blood pressure limits right-to-left shunt across the PDA and may add to right ventricular strain. In addition, the optimal therapy for reduced pulmonary blood flow is selective pulmonary vasodilation. If, instead, pulmonary blood flow is forced by elevating systemic pressure (and limiting right-to-left shunts) through the constricted pulmonary circuit, endothelial dysfunction due to increased shear stress[5] is likely to exacerbate PPHN. Dopamine (especially at >10 mcg/kg/min) is not selective to systemic vasculature and can increase pulmonary arterial pressure in PPHN.[9] Norepinephrine infusion is also effective in stabilizing systemic blood pressure and improving oxygenation in neonates with PPHN.[78] Vasopressin may be an effective therapeutic agent with some selectivity to systemic vasoconstriction.[79] Intractable catecholamine-resistant hypotension may require a dose of hydrocortisone to stabilize blood pressure in PPHN.

Temperature

Maintaining normothermia is an important supportive measure during management of PPHN. However, therapeutic hypothermia may be required in some patients with

asphyxia, PPHN, and hypoxic-ischemic encephalopathy. Asphyxia is an important risk factor for PPHN, especially if associated with meconium aspiration syndrome.[80] The use of moderate hypothermia (33.5°C for 72 hours as recommended by AAP by either whole-body cooling or selective head cooling) does not result in a significant increase in the incidence of PPHN (25% vs. 22% with conventional management without hypothermia).[81] However, as compared with moderate hypothermia (33.5°C), deeper whole-body cooling to 32°C is associated with a tendency to increased PPHN (34% vs. 25%, $p = 0.06$), increased need for inhaled NO (34% vs. 24%, p-0.03), and ECMO (9 vs 4%, p-0.005)[82] and should be avoided. Case reports indicate that patients with hypoxemic respiratory disorders before the onset of cooling (especially those that need >50% inspired oxygen and/or iNO)[83] may experience exacerbation of PPHN with hypothermia and/or rewarming.[84] Mild therapeutic hypothermia by itself is not a cause for PPHN. However, infants predisposed to elevated PVR due to the presence of asphyxia and respiratory disease may not tolerate hypothermia-induced pulmonary vasoconstriction.[85] These findings emphasize the need for close monitoring of core temperature, systemic/pulmonary hemodynamics, and oxygenation during hypothermia and rewarming for asphyxia.

In many centers, confusion exists regarding optimal reporting of $PaCO_2$ during whole-body hypothermia. The laboratory may report $PaCO_2$ levels either at baby's temperature (known as the pH-stat method) or corrected to 37°C (alpha-stat method). Decreasing temperature increases the solubility of CO_2 in the blood and decreases $PaCO_2$ and may have implications for PPHN management with potential of overventilation or underventilation. We recommend the pH-stat method and reporting of $PaCO_2$ at actual (and not corrected) body temperature.[68]

Supportive Care

All patients with PPHN benefit from a core group of therapies that includes management of hypothermia, hypocalcemia, acidosis, hypoglycemia, and polycythemia. Surprisingly, there have been few prospective randomized trials of most of the supportive therapeutic modalities advocated for treatment of PPHN. Older therapies such as hyperventilation and alkalosis were introduced into clinical practice on the basis of animal studies or short-term studies that included very small numbers of patients and used physiologic response rather than patient outcome as the end point. Only the newer therapies of inhaled nitric oxide (iNO) and extracorporeal membrane oxygenation (ECMO) have been rigorously evaluated in controlled clinical trials.

Optimal Pulmonary Hypertension During Acute PPHN Management

Animal studies documented the sensitivity of the pulmonary vasculature to both hypoxia and acidosis.[86] Short-term studies during cardiac catheterization showed reductions in PAP and elevation of oxygen tension following hyperventilation.[77,87] On the basis of these studies, hyperventilation became the mainstay of ventilation of term infants with hypoxic respiratory failure and PPHN. Subsequent observations have raised concern of impaired cerebral perfusion and neurosensory deafness at extremes of alkalosis.[88,89] Studies of infants with PPHN maintaining normal Pco_2 (40-60 mm Hg) indicate similar or better outcomes and with less chronic lung disease.[90,91]

Many neonatologists have moved away from the practice of hyperventilation in neonates with PPHN. Animal studies have shown the beneficial effects of hyperventilation result from altered pH rather than from changes in Pco_2 or minute ventilation.[92,93] At one time alkali infusion to maintain alkaline pH to induce pulmonary vasodilation was a standard practice. In a National Institute of Child Health and Human Development observational study, the group treated with alkali had a greater chance of treatment with ECMO compared with those treated with hyperventilation and an increased rate of supplemental oxygen at 28 days.[76] Alkali infusion with bicarbonate increases CO_2 production, necessitating higher ventilator support. Lack of patient outcome data with both hyperventilation and alkali infusion and availability of better therapeutic options have led to less use of these outdated management strategies. We recommend maintaining pH >7.25, preferably 7.30 to 7.40 during the acute phase of PPHN.[68]

Oxygen

Oxygen is a specific and potent pulmonary vasodilator and increased oxygen tension is an important mediator of reduction in PVR at birth. Alveolar hypoxia and hypoxemia increase PVR and contribute to the pathophysiology of PPHN. However, exposure to hyperoxia may result in formation of oxygen free radicals and lead to lung injury. Recent evidence suggests that brief exposure to 100% oxygen in newborn lambs results in increased contractility of pulmonary arteries[94] and reduces response to inhaled NO.[95,96] The biological half-life of endogenous NO is related to the local concentration of superoxide anions.[97] Administration of intratracheal recombinant human superoxide dismutase (SOD, an antioxidant that breaks down superoxide anions) results in improved oxygenation in lambs with PPHN.[98,99] On the basis of these studies, it appears that avoiding hyperoxia is as important as avoiding hypoxia in the management of PPHN.

The optimal PaO_2 in the management of PPHN is not clear. Wung et al.[91] have suggested that gentle ventilation with avoidance of hyperoxia and hyperventilation results in good outcome in neonates with respiratory failure. Decreasing PaO_2 below 45 to 50 mm Hg results in increased PVR in newborn calves[86] and lambs.[96] In contrast, maintaining PaO_2 >70 to 80 mm Hg does not result in additional decrease in PVR in both control lambs and lambs with PPHN. In animal studies, hypoxemia results in pulmonary vasoconstriction. Normoxemia reduces PVR, but hyperoxemia does not result in additional pulmonary vasodilation. But to date, randomized studies comparing different PaO_2 targets have not been conducted in infants with PPHN. We recommend maintaining preductal oxygen saturations in the low to mid-90s with PaO_2 levels between 55 and 80 mm Hg during management of infants with PPHN.[68]

Surfactant

Exogenous surfactant therapy improved oxygenation and reduced the need for extracorporeal membrane oxygenation (ECMO) in neonates with PPHN secondary to parenchymal lung disease such as MAS.[100] A post-hoc analysis of the randomized trial of early nitric oxide use showed that early use of surfactant before randomization decreased the risk of death/ECMO, especially in infants with

parenchymal lung disease.[101] Over the past decade, the use of surfactant in treating secondary PPHN and respiratory failure has increased and might have contributed to improved effectiveness of iNO with reduced need for ECMO. Surfactant inactivation and deficiency are observed in many neonatal respiratory disorders such as pneumonia, RDS, and MAS.

It is not clear if surfactant therapy is beneficial in infants with CDH. Animal studies show benefit,[102-104] but a review of the CDH registry did not support the use of surfactant.[105] We recommend administration of surfactant only in the presence of clinical, radiologic, or biochemical evidence of surfactant deficiency in CDH.

High-Frequency Ventilation

Many clinicians use high-frequency ventilation (HFV) to manage infants with PPHN. Considering the important role of parenchymal lung disease in specific disorders resulting in PPHN, adequate lung inflation and optimal ventilation are as essential as pharmacologic vasodilator therapy. In the case of inhaled vasodilators, optimal inflation and ventilation may be necessary for drug delivery.[106] Infants with PPHN from a variety of causes have been successfully treated with HFV.[107] High-frequency oscillatory ventilation (HFOV) decreases $Paco_2$ and increases oxygenation in infants with PPHN. HFOV may improve oxygenation through safer use of higher mean airway pressures to maintain lung volume and prevent atelectasis. Two studies have evaluated the effectiveness of HFV compared with conventional ventilation in rescuing infants with respiratory failure and PPHN from potential ECMO therapy.[108,109] Neither mode of ventilation was more effective in preventing ECMO in these infants. In clinical pilot studies using iNO, combination of HFOV and iNO resulted in the greatest improvement in oxygenation in some newborns who had severe PPHN complicated by diffuse parenchymal lung disease and underinflation.[110] A randomized controlled trial demonstrated that treatment with HFOV and iNO was often successful in patients who failed to respond to HFOV or iNO alone in severe PPHN, and the differences in responses were related to the specific disease associated with PPHN. Infants with RDS and MAS benefit most from a combination of HFOV and iNO therapy.[111,112] If a PIP of >28 cm H_2O or tidal volumes >6 mL/kg are required to maintain $PaCO_2$ <60 mm Hg on conventional ventilation, we recommend switching to high-frequency (jet or oscillator) ventilation.[68]

Nitric Oxide

The physiologic rationale for using iNO for treatment of PPHN[113,114] is based on its ability to achieve potent and selective pulmonary vasodilation without decreasing systemic vascular tone (Fig. 56.6). Once iNO enters the intravascular space, it combines with hemoglobin to form methemoglobin and does not exert a vasodilator effect on the systemic circulation. Inhaled NO also exerts a microselective effect and reduces V/Q mismatch. Being an inhaled vasodilator, NO enters only ventilated alveoli and redirects pulmonary blood by dilating adjacent pulmonary arterioles and reduces V/Q mismatch (see Fig. 56.6). Studies in newborn lambs have shown that prolonged administration of NO increased survival rates without increasing the incidence of acute lung injury in lambs with PPHN.[115]

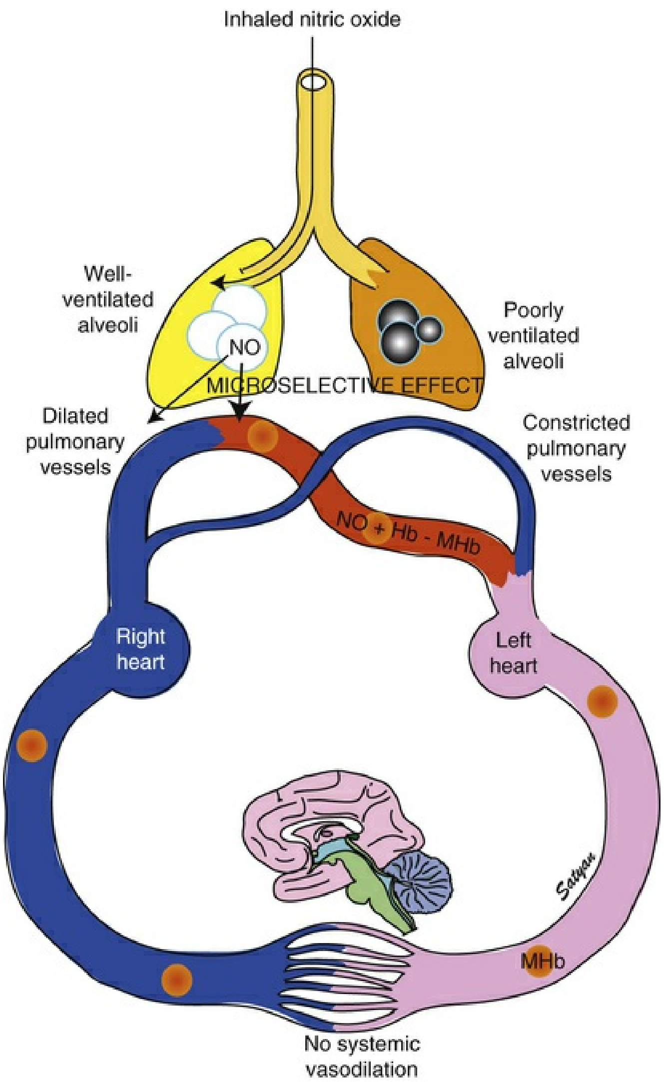

FIG. 56.6 Selective and microselective action of inhaled nitric oxide (NO). Inhaled NO is a selective dilator of the pulmonary circulation without any significant systemic vasodilation as it combines with hemoglobin to form methemoglobin (MHb). Because it is an inhaled vasodilator, it selectively goes to the well-ventilated alveoli. It improves blood flow to these alveoli and reduces V/Q mismatch (microselective effect). (Copyright Satyan Lakshminrusimha.)

Studies have shown that iNO therapy causes marked improvement in oxygenation in term newborns with PPHN.[116] Multicenter randomized clinical studies confirmed that iNO therapy reduces the need for ECMO in term neonates with hypoxemic respiratory failure.[117-119] Inhaled NO therapy is approved by the FDA for clinical use in term/near-term newborn infants (>34 weeks' gestation) with hypoxic respiratory failure and PPHN.

Initiation of iNO

There has been a debate regarding the timing of initiation and optimum starting dose of iNO in PPHN.[68] An OI of 25 is associated with a 50% risk of requiring ECMO or mortality[61] in the absence of specific pulmonary vasodilator therapy. Konduri et

al. initially demonstrated that earlier initiation of iNO with an OI of 15 to 25 did not reduce the need for ECMO but may have a tendency to reduce the risk of progression to severe hypoxemic respiratory failure.[120,121] Post-hoc analysis of the same study suggested that the use of surfactant before randomization and enrollment (and use of iNO) at an OI of ≤20 was associated with reduced incidence of ECMO/death.[101] Such early initiation is associated with fewer hospital days, fewer days on ventilation, and fewer hours on ECMO.[122]

Dosing of iNO

Previous clinical trials suggested that the ideal starting dose for iNO is 20 parts per million (ppm) with the effective doses between 5 and 20 ppm.[120] Doses >20 ppm did not increase the efficacy and were associated with more adverse effects in these infants[118] such as elevated methemoglobin (>7%) and nitrogen dioxide (NO_2) (>3 ppm).[116] A dose of 5 ppm results in improved oxygenation in PPHN. A dose of 20 ppm results in improved oxygenation *and* results in the most optimal decrease in pulmonary to systemic arterial pressure ratio.[123] To summarize, we recommend initiation of iNO if OI is ~**20** at a dose of **20** ppm. A complete response to iNO is defined as an increase in PaO_2/ FiO_2 ratio of ≥**20** mm Hg. (20-20-20 rule for initiation of iNO, Fig. 56.7).[68] Methemoglobin levels are monitored at 2 hours and 8 hours after initiation of iNO and then once a day for the duration of iNO therapy. High inspired oxygen and high mean iNO dose are risk factors for elevated methemoglobin in term infants.[124]

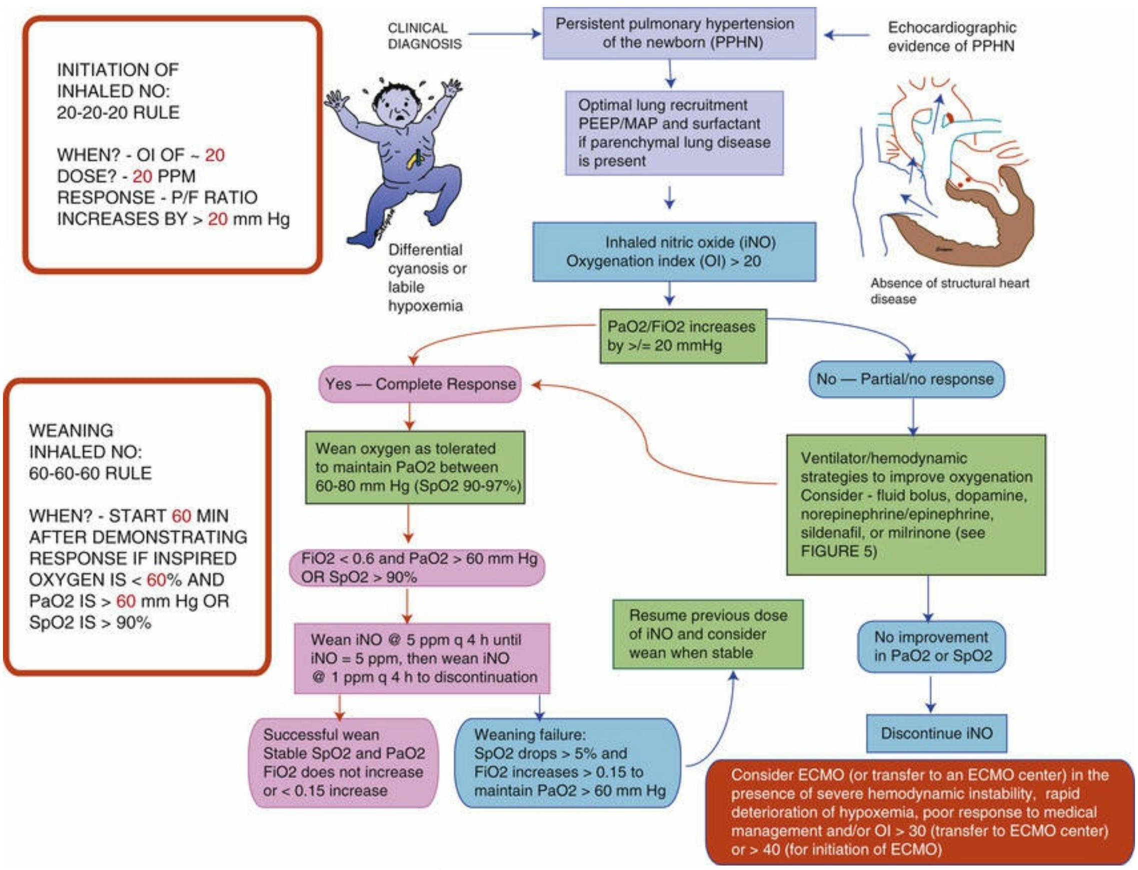

FIG. 56.7 Weaning protocol for inhaled nitric oxide in use at Women and

Weaning iNO

Due to rebound vasoconstriction and resultant pulmonary hypertension on abrupt withdrawal, iNO needs to be weaned gradually.[125] Weaning in steps from 20 ppm gradually over a period of time before its discontinuation has been shown to prevent the rebound effect.[126] If there is oxygenation response, inspired oxygen concentration is first weaned below **60**% and then iNO is weaned only if PaO_2 can be maintained ≥**60** mm Hg (or preductal SpO_2 ≥90%) for **60** minutes (60-60-60 rule of weaning iNO).[68] At our center, we wean iNO at a rate of 5 ppm every 4 hours. Once iNO dose is 5 ppm, gradual weaning by 1 ppm q 4 hours is performed (see Fig. 56.7). Continuing iNO in the absence of a response or not weaning iNO or extremely slow weaning can potentially lead to suppression of endogenous eNOS.[127,128]

Contraindications

Inhaled NO is contraindicated in the treatment of neonates known to be dependent on right-to-left shunting of blood (such as hypoplastic left heart syndrome). Also, patients with preexisting left ventricular dysfunction treated with iNO, even for short durations, have a high risk of pulmonary edema (package insert INOmax 2009).

Management of iNO-Resistant PPHN

While approximately two-thirds of patients with PPHN respond well to iNO, some do not achieve or sustain an improvement in oxygenation (Fig. 56.8).[118] Adequate lung recruitment (with surfactant and/or optimal PEEP/MAP, preferably with high-frequency ventilation) is crucial to deliver iNO to its target site—the pulmonary vasculature.[9] A repeat echocardiogram to evaluate ventricular function and severity of PPHN (and to rule out cyanotic heart disease such as total anomalous pulmonary venous return [TAPVR] that may have been missed on the first echocardiogram[69]) is the next step. Management of systemic hypotension in PPHN is discussed previously. If lung recruitment and hemodynamic stability are achieved and iNO is still not effective, the patient should be managed in a tertiary center with access to ECMO. Our recommendations for management of iNO-resistant PPHN not responding to iNO in spite of lung recruitment with increased MAP and surfactant are outlined in Fig. 56.8 and summarized here.

a. Hemodynamic evaluation: A repeat echocardiogram should be performed to exclude structural heart disease, left ventricular dysfunction, and right ventricular dysfunction and to evaluate ventricular output. For example, if left ventricular dysfunction is associated with high left atrial pressures and a left-to-right shunt at the level of the oval foramen in the presence of a right-to-left shunt at the ductus arteriosus (Table 56.1), iNO is contraindicated and an inodilator such as milrinone should be initiated.

b. Rapid deterioration with hemodynamic instability should necessitate cannulation for ECMO (or immediate transfer to an ECMO center).

c. In the presence of systemic hypotension, a fluid bolus (10 mL/kg of lactated Ringer

or isotonic saline) followed by dopamine is recommended. Some centers prefer the use of norepinephrine or vasopressin. A cortisol level is drawn in these patients. If the levels are low relative to the infant's stress level and there is no evidence of infection (viral or bacterial), the authors recommend a stress dose of hydrocortisone.

d. If blood pressure is relatively stable but hypoxemia persists, consider the use of PDE inhibitors. Sildenafil is preferred if normal liver and ventricular function are present and may have added benefit in the context of prolonged hyperoxia. Ventricular dysfunction or hepatic compromise is an indication for milrinone rather than sildenafil as long as normal renal function is present. Chronic therapy (especially in the presence of CDH or BPD) involves PDE5 inhibitors followed by endothelin receptor antagonists and noninvasive iNO (Fig. 56.8).

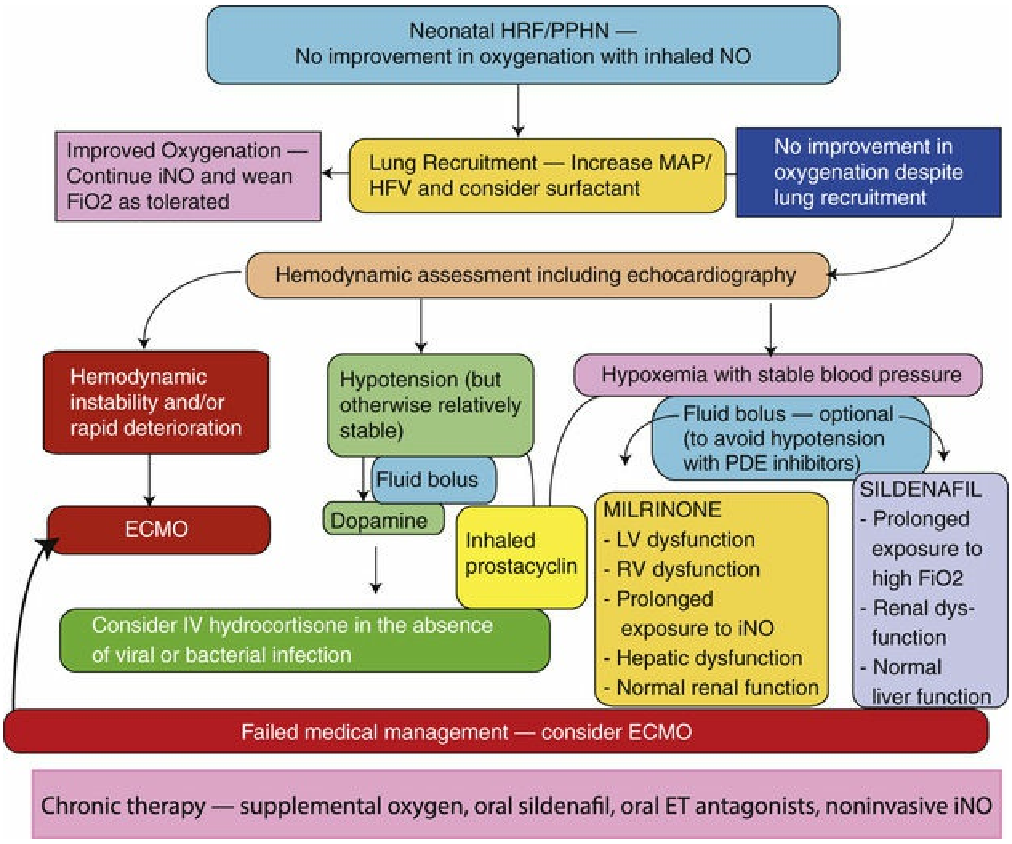

FIG. 56.8 Flowchart showing the author's suggested guidelines for management of iNO-resistant persistent pulmonary hypertension. (Copyright Satyan Lakshminrusimha.)

Side Effects of iNO

Inhaled NO by itself is toxic at higher concentrations. Potential side effects include methemoglobinemia, pulmonary edema, and platelet dysfunction. NO reacts with superoxide anion to form peroxynitrite, which causes lipid peroxidation and other oxidative injury to cell membranes. NO_2 is even more toxic. Careful monitoring of both NO and NO_2 levels during administration is mandatory.

Long-Term Outcomes Following iNO in PPHN

Outcome of infants treated with iNO collectively supports both the efficacy and safety of this mode of treatment. Reports identify significant medical and neurodevelopmental sequelae of PPHN with or without iNO and point out the necessity for coordinated multidisciplinary follow-up for these infants. The overall rate of neurodevelopmental handicap in infants treated with NO was 46%, with 25% mildly affected and 21% severely affected at age 1 year in one study.[129] In another study, mild and severe neurodevelopmental handicaps were 14% and 12% at age 1 year and 9% and 12% at age 2 years.[130] In these studies sensorineural hearing loss was present in 6% to 19% of infants with PPHN treated with iNO. No difference was noted between control and treatment groups for these outcomes. Published reports on the use of iNO in ECMO centers have not substantiated early concerns that iNO would adversely affect outcome by delaying ECMO utilization. Inhaled NO treatment may play an important role in stabilizing patients before ECMO is initiated, thus improving the chances of ECMO cannulation without further clinical deterioration. The Committee on the Fetus and Newborn, American Academy of Pediatrics, has suggested that iNO use be limited to tertiary care centers where ECMO is available.[131] In non-ECMO centers, a system should be in place to continue iNO during transport even if a response occurs, as not all physiologic responders avoid ECMO. For the same reason, the combination of HFOV and iNO should be used cautiously in non-ECMO centers.

Prostaglandin E1 (PGE1)

Aerosolized prostaglandin E1 (Alprostadil) has been used to treat pulmonary hypertension in adults. In a small pilot phase I-II study, Sood et al.[132,133] suggested that inhaled PGE1 was a safe and selective pulmonary vasodilator in hypoxemic respiratory failure with or without use of iNO. PGE1 solution for aerosolization is prepared from Alprostadil (Prostin VR 500, Pfizer, New York, New York, USA) and administered as a continuous nebulization through a MiniHeart low-flow jet nebulizer (WestMed Inc., Tucson, Arizona, USA) at 150 to 300 ng/kg/min diluted in saline to provide 4 mL/hr.[133]

IV PGE1 has also been used in patients with CDH in combination with iNO to promote pulmonary vasodilation and to maintain ductal patency and reduce right ventricular afterload.[134]

Inhaled Prostacyclin

Prostacyclin administered intravenously is a common therapy in adults with pulmonary arterial hypertension. Inhaled PGI_2 has been used in PPHN resistant to iNO at a dose of 50 ng/kg/min.[135] The IV formulation Flolan (Glaxo-Wellcome, Middlesex, UK) is dissolved in 20 mL of manufacturer's diluent (a glycine buffer, pH = 10). Fresh solution is added to the nebulization chamber every 4 hours.[135] The effect of such alkaline pH on neonatal respiratory tract is not known.

Phosphodiesterase Inhibitors

Sildenafil (PDE5 Inhibitor)

Studies have shown that cGMP is decreased in response to exogenous NO in animal models of PPHN,[136] and increased clearance of cGMP by one or more phosphodiesterases has been proposed as one of the causes.[137] Sildenafil acts by inhibiting cGMP-specific phosphodiesterase type 5 (PDE5), an enzyme that promotes degradation of cGMP. The activity of this enzyme is significantly increased following hyperoxic ventilation in lambs with PPHN.[138,139] Studies have shown that oral sildenafil (dose range 1–2 mg/kg every 6 hours) improves oxygenation and reduces mortality in centers limited by nonavailability of iNO and ECMO.[140,141]

IV sildenafil was shown to be effective in improving oxygenation in patients with PPHN with and without prior exposure to iNO.[142] The use of IV sildenafil should be restricted to refractory cases at a center with ECMO backup due to the potential risk of systemic hypotension[143] and pulmonary hemorrhage, presumably due to sudden reversal of ductal shunt.[144] On the basis of pharmacokinetic data in neonates with PPHN, IV sildenafil is administered as a load of 0.42 mg/kg over 3 hours (0.14 mg/kg/hour) followed by 1.6 mg/kg/day as a continuous maintenance infusion (0.07 mg/kg/hour).

Milrinone (PDE3 Inhibitor)

Milrinone inhibits PDE3 and increases concentration of cAMP in pulmonary and systemic arterial smooth muscle and in cardiac muscle. Milrinone relaxes pulmonary arteries in the fetal lamb model of PPHN.[145] Infants with PPHN refractory to iNO

therapy have responded to IV milrinone in three case series[146-148] and appears to be particularly useful in the presence of ventricular dysfunction.[149,150] A loading dose (50 mcg/kg over 30-60 minutes) followed by a maintenance dose (0.33 mcg/kg/min and escalated to 0.66 and then to 1 mcg/kg/min based on response) is commonly used. The loading dose is not recommended in the presence of systemic hypotension and in premature neonates.[149] As with any systemic vasodilator, hypotension is a clinical concern and blood pressure needs to be closely monitored. A fluid bolus (10 mL/kg of lactated Ringer solution) before loading dose may decrease the risk of hypotension. In addition, one case series described an increased incidence of intracranial hemorrhage with the use of milrinone in PPHN.[147] Milrinone may be the pulmonary vasodilator of choice in the presence of PPHN with left ventricular dysfunction (Fig. 56.5).

Bosentan (Endothelin-1 Receptor Blocker)

Endothelin receptor antagonists are beneficial and well tolerated in adult patients with pulmonary arterial hypertension.[151] Initial reports suggested that bosentan was an effective drug in the management of PPHN.[152] The results of a multicenter, randomized, double-blind, placebo-controlled exploratory trial of bosentan in PPHN were recently reported. Bosentan (2 mg/kg/dose twice daily) did not show any additive effect on the top of iNO in term neonates with PPHN.[153] However, endothelin receptor antagonists may have a role in the management of chronic pulmonary hypertension associated with BPD or CDH.

Steroids

Antenatal betamethasone attenuated oxidative stress and improved in vitro response to vasodilators in a fetal lamb model of pulmonary hypertension.[154] Glucocorticoids have been found to improve oxygenation and attenuate the pulmonary hypertensive response in animal models of meconium aspiration syndrome, which is a common cause of PPHN.[155] Steroids have been reported to decrease hospital stay and duration of oxygen use in infants with meconium aspiration.[156,157] It is proposed that hydrocortisone attenuates ROS production by induction of superoxide dismutase and normalization of PDE5 activity.[158] Looking at the evidence this far, we do not recommend routine use of steroids in patients with PPHN, especially if there is suspicion of viral or bacterial sepsis. Anecdotal use of stress dose hydrocortisone in iNO-resistant PPHN associated with systemic hypotension in our unit has resulted in stabilization of systemic blood pressure and improved oxygenation possibly secondary to hemodynamic stability and PDE5 inhibitory effects.[159,160]

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) is a technique of modified cardiopulmonary bypass used over a prolonged period to support heart and lung function. If the heart and lungs cannot support the newborn, they can be bypassed with ECMO. Several randomized trials have indicated improved survival of infants supported with ECMO. In a large prospective trial conducted in the United Kingdom, 121 infants with severe respiratory failure were randomized to ECMO or conventional management.[161] Survival in the ECMO-treated patients was significantly greater than in the control group (68% vs. 41%). Neurologic outcome

was similar among survivors of either treatment arm, indicating ECMO likely did not contribute to morbidity in this group of critically ill infants. ECMO has been shown to be both clinically[161] and economically[162] justifiable for mature newborn infants with severe respiratory failure. ECMO is not a specific treatment for any disease but rather a method of supportive treatment, in which the patient is kept alive while the lungs and their vasculature recover. As newer treatment modalities including HFOV, surfactant therapy, and NO have become available for treatment of hypoxemic respiratory failure, ECMO use in newborns has decreased considerably.[163,164] Because of serious inherent risks, such as systemic and intracranial hemorrhage, for infants with PPHN the procedure presently is reserved for newborn infants with reversible pulmonary disease in whom alternative therapies have failed. However, ECMO should be initiated before the infant is moribund. The technical details of ECMO including appropriate indications for venovenous (VV) versus venoarterial (VA) in PPHN are provided in Chapter 59.

The use of neonatal ECMO has declined from a peak of 1516 cases per year in 1992 to 750 to 865 cases/year from 2008 to 2012. This decline is likely due to improvements in both perinatal care and availability of advanced therapies for neonatal hypoxemic respiratory failure including high-frequency ventilators, surfactant, and iNO.[165] In newborns with PPHN, mechanical ventilation with oxygen and iNO is the initial treatment, but prolongation of iNO with high oxygen levels may induce chronic lung disease and extend the length of stay in the NICU.[166] On the other hand, initiating ECMO too early may expose newborns to major vessel cannulation and systemic anticoagulation.[167] General accepted criteria to start ECMO is persistent hypoxemia (with an OI of >40 or $AaDO_2$ >600 in spite of aggressive medical management of PPHN with mechanical ventilation and iNO) and the presence of hemodynamic instability (Fig. 57.1).

Future Therapies

Newer experimental therapies such as antioxidants, Rho-kinase inhibitors, L-citrulline, and inhaled prostacyclin analogs are under investigation. While the need for ECMO for neonates with PPHN is decreasing, this syndrome continues to be associated with high mortality and morbidity emphasizing the need for novel treatment strategies to improve outcome in PPHN.

Pulmonary Arterial Hypertension in Children

Introduction

After the newborn period, pulmonary arterial hypertension (PAH) in children is an uncommon disease characterized by elevated PAP either at rest or during exercise. Progressive obliteration of the pulmonary vascular bed with increased PVR is the hallmark of PAH and is associated with substantial morbidity and mortality. The updated classification of pulmonary hypertension (PH) (Table 56.2) has identified five groups of disorders that cause PH.[168] The groups share similar pathologic and hemodynamic characteristics and therapeutic approaches in the management of PAH. This classification represents a comprehensive, common classification for both children and adults. Pulmonary arterial hypertension can be idiopathic (IPAH) or heritable (HPAH) or associated with many other conditions listed in Table 56.2.

Group 3 encompasses developmental lung disorders, a large group of diseases unique to infants and children, who go on to develop significant lung disease, hypoxic respiratory failure, and pulmonary hypertension (see Table 56.2, section 3.7). With an estimated prevalence of 15 to 50 cases per 1 million adults, PAH is a rare disease. PAH is even less common in children, with an estimated prevalence of <10 cases per 1 million children. Five-year survival from diagnosis from a recent observational study in the United States was 74% ± 6%, with no significant difference between the idiopathic PAH/heritable PAH ($n = 122$, 75% ± 7%) and PAH associated with congenital heart disease ($n = 77$, 71% ± 13%) cohorts.[169]

TABLE 56.2

Updated Classification of Pulmonary Hypertension[168]

1. Pulmonary arterial hypertension (PAH) 1.1 Idiopathic PAH 1.2 Heritable PAH (1.2.1-BMPR2; 1.2.2-ALK-1, ENG, SMAD9, CAV1, KCNK3; 1.2.3-Unknown) 1.3 Drug and toxin induced 1.4 Associated with connective tissue disease (1.4.1), HIV infection (1.4.2), portal hypertension (1.4.3), congenital heart diseases (1.4.4), and schistosomiasis (1.4.5) 1′. Pulmonary venoocclusive disease and/or pulmonary capillary hemangiomatosis 1″. **Persistent pulmonary hypertension of the newborn (PPHN)**
2. Pulmonary hypertension due to left heart disease 2.1 Left ventricular systolic dysfunction 2.2 Left ventricular diastolic dysfunction 2.3 Valvular disease 2.4 Congenital/acquired left heart inflow/outflow tract obstruction and congenital cardiomyopathies
3. Pulmonary hypertension due to lung diseases and/or hypoxia 3.1 Chronic obstructive pulmonary disease 3.2 Interstitial lung disease 3.3 Other pulmonary diseases with mixed restrictive and obstructive pattern 3.4 Sleep-disordered breathing 3.5 Alveolar hypoventilation disorders 3.6 Chronic exposure to high altitude 3.7 Developmental lung diseases [CDH, BPD, ACD, ACD with misalignment of pulmonary veins, lung hypoplasia, surfactant protein (SP) abnormalities—SPB deficiency, SPC deficiency, ATP-binding cassette A3 mutation, thyroid transcription factor 1/Nkx2.1 homeobox mutation, pulmonary interstitial glycogenosis, pulmonary alveolar proteinosis, pulmonary lymphangiectasia]
4. Chronic thromboembolic pulmonary hypertension
5. Pulmonary hypertension with unclear multifactorial mechanisms 5.1 Hematologic disorders: chronic hemolytic anemia, myeloproliferative disorders, splenectomy 5.2 Systemic disorders: sarcoidosis, pulmonary histiocytosis 5.3 Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders 5.4 Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure, segmental PH

ACD, alveolar capillary dysplasia; *BMPR2*, bone morphogenetic protein receptor type II; *BPD*, bronchopulmonary dysplasia; *CAV1*, caveolin-1; *CDH*, congenital diaphragmatic hernia; *ENG*, endoglin; *HIV*, human immunodeficiency virus; *PH*, pulmonary hypertensiion; *SPB*, surfactant protein B; *SPC*, surfactant protein C.

Simonneau G, Gatzoulis MA, Adatia I, et al. Updated clinical classification of pulmonary hypertension. J Am Coll Cardiol. 2013;62(suppl 25):D34-41.

In a global perspective study designed to collect information on etiologies and outcomes with confirmed PAH (defined as pulmonary arterial pressures of ≥25 mm Hg; pulmonary capillary wedge pressure of ≤12 mm Hg; and pulmonary vascular resistance index ≥3 WU/m^2) from 19 countries over 2 years, 57% (182/317) had idiopathic or familial PAH. Forty-three percent (145) had PAH associated with other disorders, of which 115 had congenital heart disease (CHD). Forty-two patients (12%) had PAH associated with respiratory disease or hypoxemia, with bronchopulmonary dysplasia (BPD) being the most frequent. Chromosomal anomalies, mainly trisomy 21, were reported in 47 (13% of) patients. Median age at

diagnosis was 7 years (IQR 3-12) and 59% (268 of 456) were female. Despite severe pulmonary hypertension, 64% of these children had functional class of I or II, consistent with preserved right ventricular function.[170]

Molecular Mechanisms and Pathology of PAH

PAH is a syndrome resulting from restricted flow through the pulmonary arterial circulation, leading to pathologic increase in PVR and ultimately to right heart failure. The disease spectrum varies from mild to severe PAH, as infants and children present in various stages of PAH with symptoms related to decompensation of right ventricular function. However, the pathology appears to be restricted to the pulmonary vasculature itself. The typical pathology is mostly a progressive panvasculopathy predominantly affecting the small pulmonary arteries characterized by a variety of arterial abnormalities, including endothelial cell (EC) hyperplasia, medial hypertrophy, adventitial proliferation, thrombosis in situ, varying degree of inflammation, and plexiform arteriopathy, depending on the degree of progression of the vessel pathology. Pulmonary vascular remodeling involves structural changes in the normal architecture of the walls of PA, occurring as a primary response to injury, such as hypoxia or toxin, within the resistance PAs of the lung. The developmental phase of vascular maturation influences the degree and progression of vessel changes and also the symptomatology of PAH. A common feature of all forms of pulmonary hypertensive remodeling is the appearance of a layer of smooth muscle cells (SMC) in small, peripheral, normally nonmuscular arteries, especially the precapillary vessels, wherein the intermediate cells inside the internal elastic lamina proliferate and differentiate into SMCs. However, in vessels that lack elastic lamina (20- to 30-μ diameter), pericytes and surrounding interstitial fibroblasts contribute to the process of muscularization. In the presence of alveolar hypoxia, as in hypoxic lung disease or high altitudes, distal neomuscularization occurs, leading to formation of inner muscular tubes characteristic of hypoxia-induced PH in humans.[171,172] Increased muscularization of muscular arteries occurs in more proximal arteries, in response to endothelial damage or release of factors from endothelial cells. Activation of elastases disrupts the elastic lamina of the vessel and promotes proliferation of SMCs and deposition of extracellular matrix. Endothelial injury along with increased flow results in neointimal formation, a layer of cells between the endothelium and the internal lamina, contributing significantly to PVR. Neointimal formation is more common in congenital heart disease. It comprises cells such as myofibroblasts that lack the mature markers of SMC (such as myosin) and endothelial markers (such as CD31, CD34, or factor VIII). It has been postulated that these cells may be from the media or the adventitial fibroblasts migrating to the subendothelial space.[173] An overview of the pathologic processes occurring in the pulmonary vasculature is depicted in Fig. 56.9A.

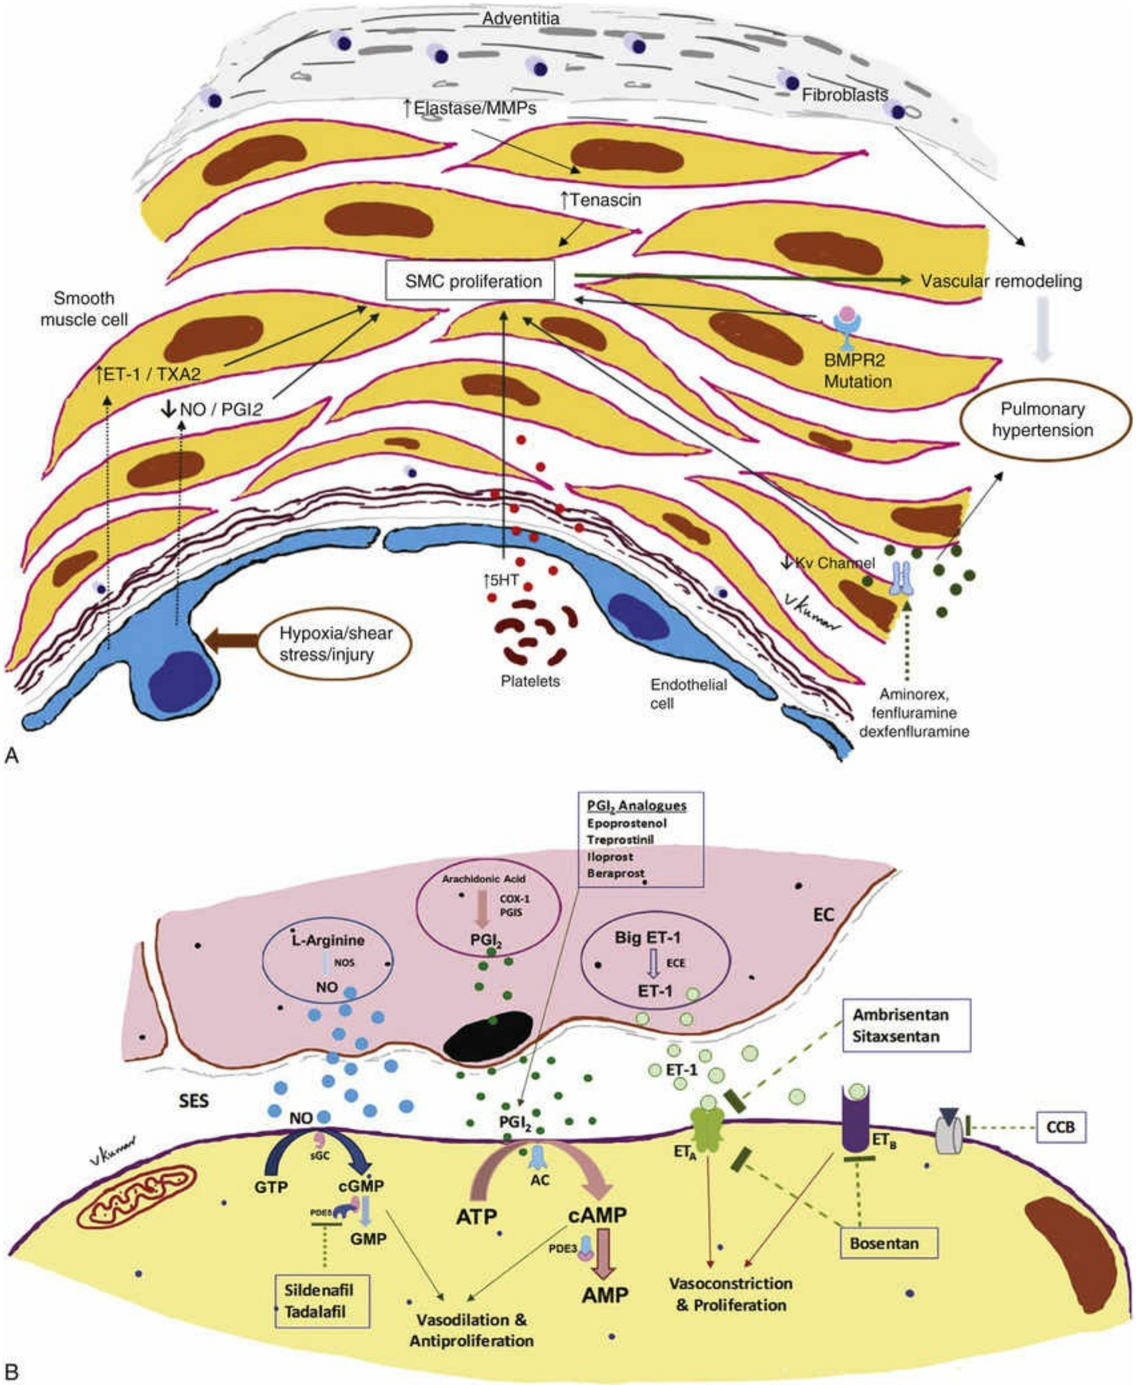

FIG. 56.9 (A) Schematic depicting the pathways involved in the pathogenesis of pulmonary arterial hypertension in children. (B) Schematic diagram of vascular mediators of the lung, their mechanism of action, interaction between the endothelial cell and the smooth muscle cell in the pulmonary vasculature and its relationship to drugs used in the management of pediatric pulmonary hypertension. The three predominant signaling pathways are shown—nitric oxide-GMP system, PGI2-cAMP system, and the endothelin-1 pathway. *AC,* adenylate cyclase; *BMPR2,* bone morphogenetic protein receptor type 2; *CCB,* calcium channel blocker; *cGMP,* cyclin GMP; *COX1,* cyclo-oxygenase type 1; *EC,* endothelial cell; *ECE,* endothelin converting enzyme; *ET-1,* endothelin-1; ET_A, endothelin receptor type A; ET_B, endothelin receptor type B; *5 HT,* 5 hydroxytryptamine; *Kv Channel,* voltage-gated potassium channel; *MMPs,* matrix metalloproteinases; *NO,* nitric oxide; *NOS,* nitric oxide

synthase; *PDE3*, phosphodiesterase type 3; *PDE5*, phosphodiesterase type 5; *PGIS*, prostaglandin synthase; *PGI_2*, prostacyclin; *SES*, subendothelial space; *sGC*, soluble guanylyl cyclase; *SMC*, smooth muscle cell; *TXA2*, thromboxane A2. See text for details. (Copyright Vasanth H. S. Kumar.)

The endothelial cell is central to the pathogenesis of PAH, translating the hemodynamic responses to histopathologic changes in the vessel wall, through a complex set of signaling mechanisms, which are still being studied. The initiating injury of the endothelial cell in PH may be hypoxia, increased flow (as in congenital heart disease), toxins, or drugs on the background of genetic susceptibility. Irrespective of the initiating process, secreted vasoactive factors direct the vascular remodeling through cell proliferation, thrombosis, and vasoconstriction. Pulmonary arterial endothelial cells from patients with IPAH produce decreased amounts of NO, a suppressor of SMC proliferation.[174] In the chronically hypoxic rat model of PH, the labeling index for endothelial cells increased threefold (measured by 3H-thymidine uptake in vivo) in main pulmonary arteries within 24 hours, and an increase in replicating endothelial cells was seen in small muscular arteries at 7 and 10 days.[175] Thus endothelial cell proliferation appears to contribute to intimal thickening, as do edema and thickening of the endothelial basement membrane.[176] In response to the stimuli (hypoxia, increased shear stress, injury), endothelial cells in the hypertensive pulmonary circulation produce more of factors such as ET-1, angiopoietin-2 (Ang-2), and thromboxane A_2 (TXA_2), which induce vasoconstriction and cell proliferation and less of mediators such as NO and prostacyclin (PGI_2), that are vasodilators and antiproliferative. The net effect of this imbalance in mediators is maintenance of the vessel wall in the remodeled hypertensive state. Hypertrophy of smooth muscle cells makes a greater contribution than hyperplasia in the larger-sized more proximal vessels, whereas hyperplasia is more prevalent than hypertrophy in the smaller resistance arteries.[176] Alterations in endothelial coagulation and fibrinolytic factors also contribute to the pathogenesis of idiopathic and thromboembolic pulmonary hypertension. In situ thrombosis in small pulmonary arteries is a feature of patients with idiopathic pulmonary hypertension. In addition, anticoagulant therapy with warfarin improves the survival of these patients. Thrombin disrupts the endothelial barrier, causing leak of proteins and interstitial edema, and promotes growth and differentiation of fibroblasts. Recent evidence supports an active role for the adventitial fibroblast in the remodeling of the pulmonary circulation during the development of pulmonary hypertension.[177]

Various stimuli can initiate vasoconstriction of the vessels of the lung in individuals with PH, predisposing these reactive vessels for subsequent development of characteristic vascular lesions.[172] The vascular endothelium is regarded as an important source of locally active mediators that contributes to the control of vasomotor tone. Thromboxane/PGI_2 and NO/ET-1 system are two of the important balances that control pulmonary vasomotor tone.

Endothelin-1 (ET-1) is a potent vasoconstrictor and stimulates pulmonary artery smooth muscle cell (PASMC) proliferation (Fig. 56.9B). Plasma levels of ET-1 are increased in PAH and correlate with severity of PAH and prognosis.[178] Of the two ET-1 receptors, ET_A receptors, expressed mainly in the smooth muscle, mediate vasoconstriction and cell proliferation, whereas ET_B receptors, expressed mainly in

the endothelial cells, are important for clearance of ET-1 and release of NO and PGI_2.[28,179] In experimental studies of hypoxia-induced[180] and monocrotaline-induced PH,[181] chronic ET receptor blockade lowered PAP and the incidence of vascular and pulmonary injury and improved NO-mediated pulmonary vasodilation. Studies with L-ω-nitroarginine methyl ester [L-NAME]–induced PH suggest that ET-1 is linked to the dysfunction of the L-arginine/NO pathway[182] because ET_A selective[183] but not combined ET blockade[184] improves endothelial function. Thus selective inhibition of ET_A receptors improves the endothelial L-arginine/NO pathway, which agrees with observations in humans.[185] ET-1 expression in pulmonary arteries is increased in patients with primary and secondary PH.[186,187] ET-1 increases at high altitudes in mountaineers and correlates with pulmonary pressures and oxygen tension.[188] ET increases even more in mountaineers prone to high-altitude pulmonary edema.[189] Increased local production[187] and elevated circulating levels of endothelin[190] have been demonstrated in patients with Eisenmenger syndrome,[191] IPAH,[192] and in PAH associated with CHD.[193]

Prostacyclin (PGI_2) is a powerful vasodilator and an inhibitor of platelet aggregation, whereas thromboxane A_2 (TXA2) is a vasoconstrictor and induces platelet aggregation leading to microvascular thrombus formation and hence vascular injury. As thromboxane A_2 and PGI_2 have opposing effects on platelet aggregation and pulmonary vascular smooth muscle, an imbalance in their biosynthesis could contribute to the progressive increase in PVR seen in older untreated patients with pulmonary hypertension from congenital heart disease.[194] Decreased urinary excretion of 2, 3-dinor-6-keto prostaglandin $F_{1\alpha}$, a metabolite of PGI_2, occurs in patients with IPAH.[195] In PAH, the balance between these two molecules is shifted toward TXA2,[195] favoring thrombosis, proliferation, and vasoconstriction. A decrease in expression of the enzyme PGI_2 synthase (PGI_2-S) in the lung may be an important manifestation of pulmonary endothelial dysfunction in severe PH. Prostacyclin synthase is decreased in small- and medium-sized pulmonary arteries, and the loss of expression of PGI_2-S may represent one of the phenotypic alterations present in the pulmonary endothelial cells in severe PAH.[196] Pulmonary PGI_2-S overexpression in transgenic mice protects against development of hypoxic pulmonary hypertension.[197] PGI_2-S may play a major role in modifying the pulmonary vascular response to injury. Intratracheal transfer of human PGI_2-S gene has been shown to augment pulmonary prostacyclin synthesis, ameliorate MCT-induced pulmonary hypertension, and improve survival in MCT rats.[198]

Potassium (K^+) channels play an important part in smooth muscle cell electrophysiology, which has implications for the development of PAH. The inhibition of voltage-gated K^+ (Kv) channels results in an accumulation of K^+ ions within the cell, depolarizing the cell and activating the voltage-gated, L-type calcium channel.[199] Intracellular calcium initiates a number of signaling cascades in the cell, leading to vasoconstriction and possibly initiating cell proliferation. Expression array analysis has demonstrated a depletion of Kv1.5 channels in pulmonary tissue derived from PAH patients.[200] It is currently unknown if these Kv channels are congenital or acquired, yet a number of polymorphisms in the Kv1.5 channel gene have been described,[201] which may suggest a genetic predisposition to channel depletion. The use of anorexic agents like aminorex, fenfluramine, and

dexfenfluramine is associated with the development of PAH,[202] and these agents are thought to act by blocking the Kv channel.[203] Kv2.1 is inhibited by dexfenfluramine, a weight-loss drug that is associated with the development of PAH.[203] Anorexigen-induced Kv channel inhibition and membrane depolarization can contribute to pulmonary vasoconstriction.[204,205] Fenfluramine reduces the Kv1.5 mRNA levels by 50% in PASMCs from normotensive patients,[206] suggesting that expression of Kv channels may play an important role in anorexigen-induced PAH. Inhibition of Kv currents in pulmonary SMCs may be regulated by serotonin, thromboxane, and nitric oxide.[176] Furthermore, BMP signaling can regulate Kv receptor expression,[207] suggesting Kv channels may represent a common pathway of regulation in pathogenesis of PAH.

An association between human immunodeficiency virus (HIV) infection and pulmonary hypertension has been noted, with a rate 6 to 12 times higher than the general population.[208] Mechanisms of disease include infection of the smooth muscle with dysregulation of proliferation, imbalance of vascular mitogens in response to systemic HIV infection, and endothelial cell injury precipitated by HIV-infected cells.[209] The direct actions of HIV-encoded proteins have also been implicated in PAH.[210] It has been thought that human herpes virus 8 (HHV-8), the causative agent for Kaposi sarcoma and an opportunistic pathogen associated with HIV, may play a role in the development of PAH, but the link has not been consistently validated.[211,212] Heightened circulating levels of cytokines and their receptors have been demonstrated in IPAH patients, including fractalkine, MCP-1, and GM-CSF.[213] Loss of BMPR2 induces IL-6, a cytokine that can cause severe PVD in rodents in association with SMC proliferation.[214] An increase in perivascular macrophages, an essential component of hypoxia-induced PAH that is seen in experimental animals, is observed in the lung tissue from patients with IPAH.[215] Matrix metalloproteinases (MMPs) and extracellular matrix are thought to be important in vascular remodeling and hence proliferation of SMCs. Endothelial abnormalities early in the course of PAH may permit extravasation of factors that stimulate SMC production of vascular serine elastase.[216,217] This results in the liberation of matrix-bound SMC mitogens, such as basic fibroblast growth factor, and enhances matrix degradation by activating other MMPs. Elevated serine elastase activity has been documented in rodent and murine models of PAH,[218] which has led to successful experimental use of elastase inhibitors to prevent the pulmonary vascular pathology. MMPs stimulate the production of mitogenic cofactor, tenascin, leading to phosphorylation of growth factor receptors and SMC proliferation. When MMPs are inhibited, tenascin levels fall, leading to apoptosis.[219] Direct inhibition of MMP-2 and serine elastases lead to complete regression of experimental PH in rats,[216] suggesting they regulate vascular tone. MMP-2 and MMP-9 can activate platelets,[220] and intravascular MMP-2 can enhance the formation of vasoconstrictors and inhibit the action of endogenous vasodilators.[220]

Genetics of PAH

More than half (70%) of patients with heritable PAH (HPAH) and 10% to 20% of patients with sporadic PAH are heterozygous for a mutation in bone morphogenetic protein (BMP) receptor type 2 (BMPR2). The penetrance of heritable PAH is low with 80% of family members carrying BMPR2 mutations not developing PAH,[221] but the functional link between BMPR2 and PAH is reinforced by the fact that IPAH

patients have reduced BMPR2 protein expression, as do some patients with other conditions associated with PAH. In addition, mutations in the TGF-β superfamily of receptors have also been described in patients with PAH and IPAH.[222] For example, activin-like kinase type I (ALK1) and endoglin are mutated in patients with hereditary hemorrhagic telangiectasia and PAH.[223,224] BMPR2 is a receptor with serine/threonine kinase activity, activating a broad range of intracellular signaling pathways. It phosphorylates one of the smad family of proteins, followed by nuclear translocation, DNA binding, and gene transcription.[225] Alternatively, it can activate via the p38/MAP kinase/ERK/JNK pathways or c-Src pathways.[226] Under normal conditions, BMP ligands bind BMPR2 to suppress the growth of vascular smooth muscle cells.[227] Failure of the protective effects of BMP ligands on endothelium may trigger vascular proliferation and remodeling. Accordingly, the proliferation of vascular SMCs[228] is facilitated by the absence of apoptosis[229] in patients with familial PAH resulting from BMPR2 mutations. Furthermore, response of pulmonary SMCs to BMP signaling appears regulated by hypoxia, a known precipitant of pulmonary hypertension.[230] Thus dysregulation of BMP signaling pathway may be a common pathogenic finding in multiple types of PAH due to genetic or exogenous stimuli.[176] The reduced expression of BMPR2 appears to be estrogen dependent as the female predisposition of IPAH is related to aberrant expression of a cytochrome, CYP1B1, which leads to a mitogenic estrogenic metabolite.[231]

Similar to BMP pathway, serotonin (5-hydroxytryptomine or 5-HT) signaling pathway has been implicated as a potential causative factor of PAH. Serotonin is both a vasoconstrictor and a mitogen that promotes SMC hyperplasia and hypertrophy.[232] It is primarily stored in the platelets and binds the G-protein–coupled serotonin receptors with intracellular action via the adenylyl-cyclase pathway. Serotonin transporter (5-HTT) transports extracellular serotonin into cytoplasm of the SMC, activating proliferation. Elevated serotonin and serotonin transport have been implicated in the pathology of experimental and clinical PAH. Serotonin exaggerates pulmonary vasoreactivity in fawn-hooded rats,[233] and there is attenuation of pulmonary vascular disease in mice lacking the serotonin transporter gene.[234] In contrast, mice overexpressing the serotonin transporter globally,[235] or specifically in SMCs,[236] develop worsened hypoxia-induced PAH. PDGF-mediated proliferation of SMCs can be compounded by increased activity of the serotonin transporter because this enhances PDGF receptor β–mediated signaling.[237]

Clinical Presentation

There is often no correlation among the time PAH is thought to have started, the age at which it is diagnosed, and the severity of symptoms. The disease seems to progress fairly rapidly, especially in children. Median age at diagnosis was 7 years (IQR 3-12 years) with 59% (268 of 456) female preponderance in the Tracking Outcomes & Practice in Pediatric Pulmonary Hypertension (TOPP) registry[170] and 4.3 ± 4.9 years (50% <2 years) from a Spanish registry.[238] Frequent tiredness, dyspnea, dizziness, and fainting spells are the typical early symptoms. Other symptoms include edema of legs, cyanosis, palpitations, and chest pain. Exertional dyspnea, chest pain, and syncope result from the inability to increase cardiac output in the presence of increased oxygen demand. Examination findings compatible with PH in children include jugular venous distention, systolic murmur of tricuspid

regurgitation, loud second heart sound at the base of the heart, and a diastolic murmur of pulmonary regurgitation. In patients with PAH and right heart failure hepatomegaly, ascites and peripheral edema may be seen. Initially the right ventricle (RV) hypertrophies to maintain cardiac output at rest, although the ability to increase cardiac output during exercise may be impaired. As pulmonary vascular disease progresses, right ventricular dysfunction ensues, resulting in right heart failure. Although the left heart is not directly affected by pulmonary vascular disease, progressive right heart dilatation can impair left ventricular filling.[239] The New York Heart Association (NYHA), the classification widely used in adults, describes the functional impact of heart failure on the degree of physical limitation. The functional level of patients is graded from I to IV with higher grades representing severe disease and worse prognosis. The NYHA classification of dyspnea was published by the World Health Organization (WHO) in 1998 as a consensus document to assess functional class in adults. The NYHA classification was graded into four classes depending on the functional ability of the patient to perform work depending on the severity of the heart disease: Class I—ability to perform work without any limitation of physical activity; Class II—slight limitation of physical activity; Class III—marked limitation of physical activity, however comfortable at rest; Class IV—inability to carry out any physical activity without discomfort. A new functional classification of pulmonary hypertension in children has been proposed because age, physical growth, and maturation influence the way in which functional effects of the disease are expressed. The classification should allow the clinician to review progress with time as the child grows up, as consistently and as objectively as possible, and to monitor response to treatment over the years. A new pediatric functional classification has been proposed for different age groups of 0 to 0.5 years; 0.5 to 1 year; 1 to 2 years; 2 to 5 years; and 5 to 16 years.[240] The following table describes the functional class through development of the child with pulmonary hypertension based on the report of the pediatric taskforce (Table 56.3).[240]

TABLE 56.3

Functional Classification for Assessment of Pulmonary Hypertension in Infants and Children Up to 16 Years of Age[240]

Age	Class I	Class II	Class IIIa	Class IIIb	Class IV
0-6 Months	Asymptomatic, growing and developing normally, no limitation of physical activity; has head control with normal body tone; rolls over & has no head lag. Sitting with support	Slight limitation of physical activity, unduly dyspneic and fatigued; falling behind physical developmental milestones; growing along centiles	Marked limitation of physical activity, unduly fatigued; comfortable at rest; regression of learned physical activities; quiet & needs frequent naps; less than ordinary activity causes undue fatigue, syncope, or presyncope; growth compromised; poor appetite; requires excessive medical attention	Growth severely compromised; poor appetite; supplemental feeding; less than ordinary activity causes undue fatigue or syncope + features of Class IIIa	Unable to carry out any physical activity without undue dyspnea, fatigue, or syncope; not interacting with family; syncope and/or right heart failure + features of Class III
6-12 Months	Mobile, sitting, grasping, starting to stand, crawling, playing	Delayed physical development; growing along centiles; comfortable at rest	Regression of learned physical activities; stops crawling; quiet and needs frequent naps; hesitant, cautious & unadventurous; growth compromised; poor appetite; comfortable at	Growth severely compromised; poor appetite; supplemental feeding; less than ordinary activity causes undue fatigue or syncope + features of Class IIIa	Unable to carry out any physical activity without undue dyspnea, fatigue, or syncope; not

			rest; less than ordinary activity causes undue fatigue or syncope; requires excessive medical attention		interacting with family; syncope and/or right heart failure + features of Class III
1-2 Years	Standing, starting to walk/walking, climbing	Delayed physical development; unduly dyspneic & fatigued when playing; continues to grow along centiles	Regression of learned physical activities; reluctant to play; quiet & needs frequent naps; hesitant, cautious & unadventurous; growth compromised; poor appetite; less than ordinary activity causes undue fatigue or syncope; comfortable at rest	Growth severely compromised; poor appetite; supplemental feeding; less than ordinary activity causes undue fatigue or syncope + features of Class IIIa	Unable to carry out any physical activity without undue dyspnea, fatigue, or syncope; not interacting with family; syncope and/or right heart failure + features of Class III
2-5 Years	Asymptomatic, growing normally; attending nursery/school regularly, playing games with his/her peers	Unduly dyspneic & fatigued when playing with friends; nursery/school attendance—75%; no chest pain	Regression of learned physical activities; reluctant to play with friends; comfortable at rest; nursery/schooling compromised (<50% attendance); less than ordinary activity (dressing) causes undue dyspnea, fatigue, syncope, or chest pain	Unable to attend nursery/school, but mobile at home; wheelchair needed outside home; growth compromised; poor appetite; supplemental feeding; less than ordinary activity causes undue fatigue, syncope, or chest pain + features of Class IIIa	Unable to attend school, wheelchair dependent, not interacting with friends; syncope/chest pain and/or right heart failure + features of Class III
6-15 Years	Asymptomatic, growing along centiles; children attending school regularly, playing games with his/her peers	Unduly dyspneic & fatigued when playing with friends; school attendance 75% normal; no chest pain; comfortable at rest	No attempts at sports; comfortable at rest; schooling compromised (<50% attendance); less than ordinary activity causes undue dyspnea, fatigue, syncope, or chest pain	Unable to attend school but mobile at home and interacting with friends; wheelchair needed outside the home; growth compromised; poor appetite; supplemental feeding; less than ordinary activity (dressing) causes undue dyspnea, fatigue, syncope and/or presyncope, or chest pain + features of Class IIIa	Unable to attend school, wheelchair dependent, not interacting with friends; syncope/ chest pain and/or right heart failure + features of Class III

Lammers AE, Adatia I, Cerro MJ, et al. Functional classification of pulmonary hypertension in children: report from the PVRI Pediatric Taskforce, Panama 2011. Pulm Circ. 2011;1:280-285.

Diagnostic Approach

The diagnosis of PAH is made on the basis of a clinical and a comprehensive diagnostic evaluation. Chest radiographs, pulmonary function tests (PFTs), and sleep study will help in ruling out pulmonary causes of PH. Chest radiographs may demonstrate enlarged central pulmonary arteries, right heart enlargement, or evidence of left-sided heart lesion. Etiologic clues of parenchymal lung disease or an airway lesion may be demonstrated. PFT and exercise testing are important for not only diagnosis but also monitoring progression of the disease. Other tests that may help in the diagnosis include autoantibody testing for collagen vascular disorders, HIV testing, and LFTs in cases of portopulmonary hypertension. Electrocardiographic abnormalities are common in pediatric PAH. Right axis deviation (RAD) and right ventricular hypertrophy (RVH) on electrocardiogram are commonly associated with worse hemodynamics, whereas their absence is suggestive of a lack of disease progression.[241] In catheterization-confirmed PAH patients ≤18 years of age, 93% had an electrocardiographic abnormality, with 78%

demonstrating RVH and 52% had RAD for age.[241] If PH is suspected on the basis of history, risk factor assessment, and physical examination, an echocardiogram is the next appropriate study.

Doppler echocardiography may offer clues to the potential etiologies of PH, particularly left-sided heart lesions. However, tricuspid or pulmonary regurgitation velocity measurements with pulsed Doppler are more reliable in determining the presence of pulmonary hypertension.[242] Right ventricular systolic pressures >35 to 40 mm Hg in a patient with unexplained dyspnea may warrant further evaluation of PAH. A Doppler-derived ratio of tricuspid regurgitation velocity (TRV) to velocity time integral (VTI) of the right ventricular outflow tract (RVOT) [TRV/VTI_{RVOT}] is a simple, noninvasive method to estimate PVR and can be used to follow up patients post catheterization and to assess response to treatment.[243] Common echocardiographic findings of PAH include right atrial and right ventricular (RV) enlargement, reduced RV function, tricuspid regurgitation, flattening of intraventricular septum, and underfilling of the left ventricle. Despite limitations and interobserver variability, findings on echocardiography strengthen the diagnosis of PAH; however, right heart catheterization (RHC) will eventually be required for an accurate assessment of PVR and to confirm the diagnosis. Other noninvasive modalities such as CT and/or MRI should be explored before subjecting the patient to a catheterization procedure. CT scanning may suggest an etiology of PAH such as a severe airway or parenchymal lung disease. Chronic thromboembolic pulmonary hypertension (CTEPH) is a form of PH and should be sought in all patients with clinically significant PH because it is curable with surgery. CT and V/Q scans help in the diagnosis of CTEPH. Presence of ground-glass opacities, particularly with a centrilobular distribution, septal lines, and adenopathy on CT scan, are suggestive of pulmonary veno-occlusive disease in a patient displaying symptoms of PH.[244] Pulmonary veno-occlusive disease is an unusual form of PH, characterized by elevated PAP with a normal pulmonary capillary wedge pressure and evidence of venous congestion on CXR. Cardiac MRI accurately assesses size and function of the RV with a high degree of reproducibility and hence is used a prognostication tool in the management of PAH.[245] Despite the previously mentioned noninvasive investigations, catheterization may be necessary to define the hemodynamic profile, confirm the diagnosis of PAH, perform vasoreactivity testing on confirmation of diagnosis, and, most importantly, begin a specific management plan for the treatment of PAH.

The current hemodynamic definition of PAH is a mean PAP ≥25 mm Hg, a pulmonary capillary wedge pressure (PCWP), left atrial pressure (LAP) or left ventricular end-diastolic pressure (LVEDP) of ≤15 mm Hg, and a pulmonary vascular resistance index (PVRI) of ≥3 Wood units/m.[2,246] Any patient with suspected PAH requires a careful invasive assessment of pulmonary hemodynamics, as elevated PA pressure is not always caused by pulmonary vascular disease. Pulmonary hypertension commonly occurs with high transpulmonary flow states such as exercise, anemia, pregnancy, sepsis, portopulmonary syndrome, or thyrotoxicosis. In these states, the pulmonary vascular bed is anatomically normal and the PH resolves when the cardiac output returns to normal. The consensus document on pulmonary hypertension requires elevated PVR as opposed to simply elevated mean PAP in the setting of normal left heart filling pressures. PVR is a more robust diagnostic criterion for PAH because it reflects the influence of

transpulmonary gradient and cardiac output and is only elevated if the vascular obstruction occurs within the precapillary pulmonary circulation. PVR is a useful measure to apply to patients with increased mean PAP. PVR distinguishes passive PH (elevated mean PAP, normal PVR) from PAH caused by pulmonary vascular disease (elevated mean PAP, elevated PVR). By definition, PVR and PAP are both elevated in PAH.[247]

All patients suspected of having PAH after noninvasive evaluation should undergo right heart catheterization before initiation of therapy specific to PAH. Although RHC and pulmonary angiography are invasive, they can be performed safely by experienced operators even in patients with severe PH and right heart failure. In a recent review of 7218 RHC procedures collected retrospectively and prospectively, 76 (1.1%) serious events were reported. Most of them were related to venous access (hematoma, pneumothorax), followed by arrhythmias and hypotensive episodes related to vagal reactions or pulmonary vasoreactivity testing with an overall procedure related mortality of 0.05% (4/76).[248] In a recent review, the mean age of cardiac catheterization (CC) for PHVD was 4 years (0.3-17), with 75 patients undergoing 97 CC. Twenty-nine percent of the patients had heritable PAH, and 52% had CHD with 14% with lung disease.[249] No deaths or serious arrhythmias were noted in any patients. Three percent of patients undergoing CC had adverse events, and 45% of patients from follow-up CC resulted in alteration of therapy. A simple but not an exhaustive workup of the child with suspected pulmonary hypertension is illustrated in Fig. 56.10.

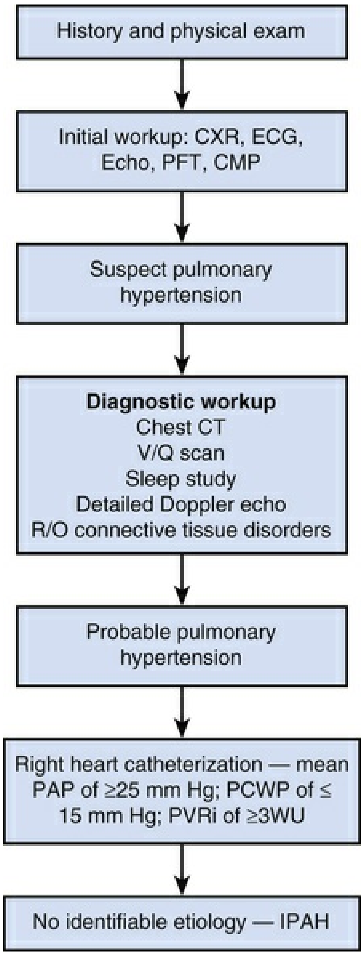

FIG. 56.10 Algorithm for diagnostic workup for pulmonary hypertension in children. *CMP,* comprehensive metabolic panel; *CT,* computed tomography; *CXR,* chest radiograph; *ECG,* electrocardiogram; *Echo,* echocardiogram; *IPAH,* idiopathic pulmonary arterial hypertension; *PAP,* pulmonary artery pressure; *PCWP,* pulmonary capillary wedge pressure; *PFT,* pulmonary function tests; *PVRi,* pulmonary vascular resistance index; *V/Q,* ventilation-perfusion scan.

Acute Vasodilator Testing

Vasodilator testing establishes the relative contribution of reversible vasoconstriction versus fixed stenosis in patients with PAH over a brief period of minutes to hours, and this can be used as a screen to identify patients who may benefit from long-term therapy with oral calcium channel blockers (CCBs). Responders seem have better prognosis than nonresponders.[250] Acute vasodilator testing (AVT) is usually performed during diagnostic catheterization using inhaled NO,[251] IV PGI_2,[252] or IV adenosine.[253] The decision to proceed with AVT has to be individualized; however, patients with idiopathic PAH or congenital heart disease often benefit the most from this testing. Patients with PAH secondary to connective tissue disorders, NYHA functional class IV, and elevated left heart filling pressures or those on calcium channel blockers are not candidates for vasodilator testing.[254] Significant response to acute vasodilator has been complicated by a variety of definitions, such as a decrease in mPAP by at least 10 mm Hg to an absolute level of <40 mm Hg without a decrease in cardiac output[255]; a fall in PVR of ≥30%[256]; or a decrease of >20% in both mPAP and

PVRI.[257] The percentage of positive tests depends on the criteria used and is about 10% to 15%.[258] Half of the patients with a positive test will benefit from long-term therapy with CCBs.[259]

Inhaled NO is the commonly used drug for AVT at doses of 10 to 80 ppm for 15 minutes,[257] but the vasodilator response to NO is not dependent on the concentration and most of the response is obtained at 10 ppm with 2 minutes of inhalation.[256] Acute vasodilator testing with inhaled treprostinil at a dose of 1.5 μg/kg (0.7–2.9 μg/k) has recently been shown to be well tolerated in children with PAH.[260] Other drugs such as inhaled iloprost at doses of 5 to 50 μg in 10 to 15 minutes have been tested with good results.[261] A positive test estimates the degree of vasoconstriction at a given time, but it does not predict the activity of the underlying disease process. It is possible that those patients who have a significant vasodilation but later fail chronic CCB therapy have a more aggressive form of the disease. In patients with IPAH and positive pulmonary vasoreactivity test, CCBs have a pulmonary vasodilator effect with reduction in mPAP and increase in quality of life and survival.[255] The current approach is to initiate CCBs if the patient has a positive vasodilator test, adequate systemic blood pressure, and stable dyspnea in NYHA class I to IV before initiation of therapy.[262]

Treatment

The prognosis of children with PAH has improved in the past decade owing to new therapeutic strategies and aggressive treatment strategies. Although management decisions were often extrapolated from adult studies, emerging literature from pediatric clinical trials helps in forming management decisions specific to children. The natural history of idiopathic PAH in children is worse than adults; however, with treatment, the outcome appears to be better in children. The ultimate goals of treatment should be improved survival and allowing for maximum activities of childhood without any limitations. Improvement in symptomatology (dyspnea, fatigue, and chest pain) and hemodynamic profile (lowered PAP) help in preventing the progression of the disease and improve survival.

Management of Acute Exacerbation of PAH

Clinically significant deteriorations of PAH such as progressive worsening of symptoms, syncope, right ventricular failure, or postoperative PAH need prompt diagnosis and management in order to decrease morbidity and mortality associated with acute PAH.

Oxygen

As hypoxemia is a potent pulmonary vasoconstrictor, it is recommended to start supplemental oxygen to maintain oxygen saturation ≥90%. O_2 supplementation is used to avoid acute/chronic hypoxemia and is considered in patients with severe right heart failure or hypoxemia following exercise and in nonhypoxic patients in exacerbation.[263] Some patients may benefit from chronic O_2 supplementation as home therapy along with maintenance therapy with medications to slow the progression of the disease.[264]

Nitric Oxide

Nitric oxide (NO) is currently the first-line drug in the acute management of PAH or in cases of postoperative PAH arising from CHD repair or other causes. Nitric oxide is produced endogenously in the vascular endothelium. It acts by increasing cGMP in the smooth muscle by stimulating guanylate cyclase, relaxing the smooth muscle, and contributing to reduced PAP and hence PVR. Inhaled NO (iNO) dilates the pulmonary circulation, deactivated by combining with hemoglobin while avoiding systemic vasodilation, and is extremely effective in the management of PH in critically ill patients in intensive care setting.[265] Inhaled NO, however, is expensive and requires a fairly sophisticated delivery and monitoring system. Inhaled nitric oxide has been used to assess the vasodilator capacity of the pulmonary vascular bed in children with CHD and elevated PVR.[266,267] Low-dose iNO (2–20 ppm) has been effective in the management of postoperative PH following corrective surgery in infants with CHD.[268]

The acute responsiveness to iNO seems to predict the subset of patients who might be responsive to oral calcium channel blockers and thus is a relatively safe and easy test to perform during cardiac catheterization.[269] NO at higher doses (20–80 ppm) produces selective pulmonary vasodilatation in children with CHD and PH.[270] In a randomized trial, high-risk infants undergoing congenital heart surgery, prophylactic use of NO at 10 ppm continuously until extubation had fewer pulmonary hypertensive crises compared with controls.[271] It can help discriminate anatomic obstruction to pulmonary blood flow from pulmonary vasoconstriction and may be used in the treatment or prevention of pulmonary hypertensive crisis after cardiopulmonary bypass in neonates.[272,273] A trial of iNO may diminish the need for ECMO in patients with cardiopulmonary failure following cardiac surgery.[274,275] Inhalation of low levels of NO appears to be safe. The major clinical toxicity is due to the formation of NO_2 and methemoglobinemia.

Maintenance Therapies of PAH in Children

Conventional Therapies

The therapeutic regimen must be tailored in a given child and adjusted according to the clinical and hemodynamic response to improve the quality of life in children with PAH. Most important are avoidance and treatment of chronic hypoxemia. As hypoxemia is a potent pulmonary vasoconstrictor, it is recommended to maintain oxygen saturation ≥90% during the chronic phase of the disease. Children are advised to avoid heavy physical exercise because this may evoke exertional syncope and to be on O_2 supplementation to avoid chronic hypoxemia following exercise. A sodium-restricted diet is advised and is particularly important to manage volume status in patients with RV failure. Diuretic therapy is often necessary in children with heart failure but should be initiated carefully. Children with PAH may be preload dependent to maintain adequate cardiac output. The use of diuretics remains essential in the management of patients with PH related to left ventricular dysfunction.[276] Although its role is not well studied in children, chronic anticoagulation may be beneficial in patients with low cardiac output states, central venous lines, or hypercoagulable states at risk for thrombosis in situ. Risks and benefits of anticoagulation should be weighed, particularly in young children, who

are at risk of hemorrhage. The use of anticoagulation in Eisenmenger physiology is controversial—it has not been shown to impact long-term survival.[277]

Routine immunizations, such as against influenza and pneumococcal pneumonia, are advised. Current guidelines recommend that pregnancy be avoided or terminated early in women with PAH,[255] as hemodynamic fluctuations of pregnancy and labor are potentially devastating to PAH patients with a maternal mortality of 30% to 50%.[278] It is important to discuss effective methods of birth control with women with PAH of child-bearing potential, although the preferred method is not clear. Furthermore, it is better to avoid major elective surgeries, especially during periods of progression or bad control of the disease. Therapy in secondary pulmonary hypertension is directed at the etiology of PAH. Closure of the heart defect will resolve the PAH secondary to increased pulmonary blood flow. Management of pulmonary venous hypertension includes controlling left ventricular failure and relieving the cause of venous obstruction (commonly left heart obstructive lesions). Vasodilator therapy is the mainstay in management of PAH, and even small reductions in right ventricular (RV) afterload following vasodilator therapy will produce substantial improvement in RV output. The goal of vasodilator therapy is to reduce PAP and increase cardiac output without symptomatic systemic hypotension.

Calcium Channel Blockers

Historically, calcium channel blockers (CCBs) were the drugs primarily used in the treatment of PAH in the absence of alternate therapy. By inhibiting calcium influx into cardiac and smooth muscle, CCBs cause relaxation of the vascular smooth muscle but may decrease cardiac contractility. Acute response to the vasodilator drug during cardiac catheterization will help in determining the desirability of using chronic oral CCBs. The response to acute vasodilator testing is higher in children compared with adults (41% vs. 12% in adults).[279] The acute response in children is also age dependent. Patients who meet criteria for oral CCBs should be followed closely for both safety and efficacy of CCB therapy. CCBs should be avoided in patients with severe ventricular dysfunction, high right atrial pressures, and decrease in cardiac output and in patients <1 year of age. If the patient meets the definition of an acute response and does not improve to functional class I or II on CCB therapy, he or she should not be considered a chronic responder and alternative PAH therapy should be considered. Long-acting nifedipine, diltiazem, and amlodipine are the most commonly used calcium channel blockers. Verapamil should be avoided due to its potentially negative inotropic effects. Oral CCBs help in reducing PAP in about 40% of children with PAH.[280] In the remaining 60%, acute vasodilator testing with agents such as iNO or IV PGI_2 failed to demonstrate responsiveness and these children have not benefited from chronic oral CCB therapy.[280] Chronic CCB therapy improved survival and quality of life in children who acutely respond to vasodilator drug testing.[281] A 5-year survival rate for patients treated with chronic oral calcium channel blockade who respond acutely to vasodilator testing was 97% versus 35% for those who do not respond acutely.[280] Regular, noninvasive monitoring of PAP and cardiac function is as essential part of the management of patients on chronic CCBs, as they may deteriorate over time. Chronic use of calcium channel blockers in patients with fixed PVR and unfavorable

hemodynamics may worsen right heart failure.

Prostacyclin Agonists

Prostacyclin (PGI_2) increases cAMP by stimulating the enzyme adenylate cyclase within the vascular smooth muscle, resulting in vasodilatation. Prostacyclin is reduced in patients with PAH and administering PGI_2 or its analogs has been the mainstay in the management of these patients. Currently commercially available prostanoids include epoprostenol, treprostinil, iloprost, and beraprost.

Epoprostenol

Prostacyclin (sodium epoprostenol) has been studied extensively over the past decade. Long-term, continuous IV PGI_2 has been shown to improve survival, quality of life, and exercise capacity and to significantly reduce PAP in children with PAH.[279,280,282,283] Until recently, chronic IV PGI_2 was the mainstay of PAH in children who were not considered responders to vasodilator testing. In both nonresponders and responders who fail to improve on CCBs, continuous IV infusion with PGI_2 improved survival.[280] Since the consistent availability of epoprostenol, the survival of children with idiopathic PAH at 1, 5, and 10 years was 97%, 97%, and 78% with a treatment success rate of 93%, 86%, and 60%, respectively.[284] Chronic PGI_2 therapy lowered mPAP, PVR, and quality of life in patients with PH and associated CHD who failed conventional therapy.[285] Children are on PGI_2 therapy for months to years, depending on the progression of the disease and patient needs. Some children who were previously believed to have fixed pulmonary vascular disease with irreversible obstruction may be reversible with long-term IV PGI_2, perhaps via remodeling of the pulmonary vascular bed.[280,286] However, epoprostenol has a short half-life (2-3 minutes), necessitates administration by continuous IV administration and placement of a central catheter, and is delivered by a portable infusion pump. Due to a complicated nature of delivery mechanism, epoprostenol therapy should be initiated at a specialist center, well versed in PGI_2 administration. Epoprostenol is initiated at a dose of 1 to 3 ng/kg/min and scaled up over days to weeks to a maintenance dose of 50 to 80 ng/kg/min. Side effects are dose dependent, occurring within hours of dose titration, and commonly include flushing, headache, jaw pain, diarrhea, and thrombocytopenia.[287,288] Despite its short half-life, it has a potential for systemic hypotension from high doses and significant desaturations from ventilation-perfusion mismatching in patients with significant lung disease.[276] Tolerance develops in some patients requiring dose escalation, resulting in additional adverse events and increased drug costs. More importantly, complications are associated with administration of PGI_2 such as risk of serious infections, catheter thrombosis, and rebound PAH due to pump failure with subsequent interruptions in therapy.[289,290] Given its considerable complexity, epoprostenol use should be limited to centers experienced with its administration and systematic follow-up of these patients. Although in the late 1980s and early 1990s, the aim of chronic PGI_2 therapy was to act as a bridge to lung or heart/lung transplantation,[291] currently continuous PGI_2 is being used as an alternative therapy to transplantation in selected children.[279]

Treprostinil

The propensity for serious catheter-related infections with epoprostenol administration led to the development of treprostinil, a stable prostacyclin analog for management of PAH. Its administration was initially approved for subcutaneous infusion followed subsequently by intravenous and inhaled routes. Treprostinil has a longer half-life (about 4 hours), stable at room temperatures with fewer side effects. Treprostinil delivered by subcutaneous route (40 ng/kg/min) demonstrated a significant improvement in functional class, hemodynamics, and 6-minute walk (6MW) distance, suggesting it has the potential for rescue therapy in children.[292] Bloodstream infection with PGI_2 is one of the reasons for switching to subcutaneous treprostinil. Although injection site pain due to subcutaneous infusion remains a major disadvantage, subcutaneous treprostinil may be tolerated in children.[292] In a recent study, children with PAH were successfully switched to IV treprostinil to decrease side effects from IV PGI_2.[293] Recently inhaled treprostinil has shown promising results.[294,295] Children with PAH received three to nine breaths (6 μg/breath) of inhaled treprostinil four times/day. Inhaled treprostinil was associated with improvement in exercise capacity and WHO functional class when added to background-targeted PAH therapy in children. Side effects include cough and sore throat, occasionally needing discontinuation of treatment.[294] In PAH patients who remained symptomatic on bosentan or sildenafil, inhaled treprostinil improved exercise capacity and quality of life and was safe and well tolerated.[295] Inhaled treprostinil is currently used as an add-on therapy for progressive PAH or with serious effects with another drug. IV or subcutaneous treprostinil is generally started at 1.25–2 ng/kg/min and gradually increased to 50–80 ng/kg/min on the basis of clinical status, hemodynamic profile, and side effects. Given the complexity of administration of both IV and subcutaneous treprostinil, administration should be limited to centers experienced with this agent. The Centers for Disease Control and Prevention report raised concern for an increased risk of bloodstream infections, particularly with gram-negative organisms, in patients receiving IV treprostinil.[296] Despite the concerns with treprostinil remaining the same as with IV epoprostenol, the availability of subcutaneous, IV, and inhaled preparation and fewer side effects allow for greater flexibility in the management of PAH in children.

Iloprost

Iloprost is a stable prostacyclin analog with a serum half-life of 20 to 25 minutes. Aerosolization of prostacyclin or its stable analog iloprost causes selective pulmonary vasodilatation, increases cardiac output, and improves venous and arterial oxygenation, probably by minimizing ventilation-perfusion mismatch in patients with severe PH.[297] Inhaled iloprost represents a significant advance from IV PGI_2 in the management of PAH, offering a new strategy for treatment of this disease. Long-term treatment with aerosolized iloprost has been shown to be safe and has sustained effects on exercise capacity and pulmonary hemodynamics in patients with PPH.[298] In a placebo-controlled trial, iloprost inhalation (2.5 μg or 5 μg per inhalation; median dose of 30 μg per day) improved pulmonary hemodynamics and quality of life in patients with severe PH.[299] Inhaled iloprost might be an alternative to iNO for early testing of vascular reactivity and postoperative treatment of acute PH in children with CHD.[300-303] Common side effects of inhaled iloprost

include cough, headache and flushing, and jaw pain. Iloprost was approved by the FDA in 2004 for functional class III and IV PAH. Its short half-life and frequent inhalations (six to nine times daily) do not make it an ideal candidate for chronic treatment of PAH in children.

Beraprost

Beraprost is a prostacyclin analog for oral administration. It has been shown that beraprost reduces PVR in patients with PAH[304-306] and may also be effective in the treatment of secondary precapillary pulmonary hypertension.[307] Oral administration of beraprost sodium may also improve exercise capacity and ventilatory efficiency in patients with both primary and chronic thromboembolic pulmonary hypertension.[308] In a randomized study, beraprost (80 μg four times a day) improved exercise capacity and symptoms in NYHA functional class II and III patients with PAH and, in particular, in those with primary pulmonary hypertension.[309] Limited studies suggest the efficacy of oral beraprost in infants and children with PH secondary to congenital heart defects.[310]

Endothelin Receptor Antagonists

Endothelin-1 mediates vasoconstriction and smooth muscle cell proliferation contributing to the development of PAH. Its action is mediated mainly through the ET_A receptor. Both nonselective (ET_A and ET_B receptor) and selective (ET_A receptor) antagonists are being evaluated in animal and clinical studies.

Bosentan

Bosentan, a dual endothelin receptor antagonist and an oral antagonist of both ET_A and ET_B receptors, is the most widely studied endothelin receptor antagonist (ERA) in clinical trials. Several clinical studies in children have demonstrated the usefulness of bosentan therapy, including an improvement in exercise capacity, functional class, and long-term outcomes in idiopathic PAH and PAH associated with CHD.[311-314] In one of the first studies published in children, the risk of worsening was lower in patients in WHO functional class I/II than in patients in WHO class III/IV at bosentan initiation with Kaplan-Meier (K-M) for survival at 2 years of 91%[315] and the K-M estimate for disease progression of 54% at 4 years.[316] In another large observational study, bosentan was safe and effective in slowing the progression of the disease.[317] Bosentan, when administered over 3 years in patients with IPAH or associated with CHD, led to improvement in both functional class and 6MW distance up to 3 years. After 3 years, bosentan was continued as monotherapy in only 21% of children with IPAH but in 69% of repaired cases and 56% of those with Eisenmenger syndrome. K-M survival estimates for the 101 patients studied were 96%, 89%, 83%, and 60% at 1, 2, 3, and 5 years, respectively.[317]

The Bosentan Randomized Trial of Endothelin Antagonist Therapy-5 (BREATHE-5) was a 16-week, multicenter, randomized, double-blind study evaluating the effect of bosentan on systemic pulse oximetry and pulmonary vascular resistance in patients with WHO functional class III Eisenmenger syndrome.[318] Bosentan was used at a dose of 62.5 mg twice daily for 4 weeks followed by 125 mg twice daily for the duration of the study. In this first placebo-controlled trial in children with ES, bosentan was well tolerated and improved exercise capacity and hemodynamics

without compromising peripheral oxygen saturation. The lack of changes in the SpO_2 was due to similar decreases in PVRi and SVRi, resulting in a limited impact on right-to-left shunt. The reductions in hemodynamic parameters such as PVR index (PVRi), SVR index (SVRi), mPAP, and SBP might have decreased the workload on the right and left ventricles and contributed to the delay in the progression of right ventricular failure.[318] Side effects in the bosentan-treated group were comparable with those reported in the literature and include edema, palpitations, headache, chest pain, and elevated liver enzymes.[318] Potentially serious hepatotoxicity and teratogenicity has been reported with bosentan, which requires close monitoring and cautious use. Due to the risk of hepatic toxicity, the FDA requires that liver function tests be performed at least monthly and hematocrit every 3 months on these patients. Experts are concerned that endothelin antagonists as a class may be capable of causing testicular atrophy and male infertility. Younger males who may consider conceiving should be counseled regarding this possibility before taking these drugs. In a pharmacokinetic assessment of bosentan in pediatric PAH (pediatric FormUlation of bosenTan in pUlmonary arterial hypeRtEnsion–FUTURE-1 study), plasma concentration of bosentan in children was lower than in adults despite doubling the dose from 2 mg/kg bid to 4 mg/kg bid, suggesting exposure plateau is reached at 2 mg/kg twice daily. This could be related to a smaller size of their intestinal surface area or other absorption characteristics resulting in lower absorption, given that elimination half-life was similar in both children and adults.[313] It is worth noting that after an oral administration, maximum concentrations are reached in 3 to 5 hours with elimination half-life of 5 hours. Bosentan is metabolized primarily by CYP2CP and 3A4 isoenzymes in the liver, and its metabolites are excreted in the bile. The new pediatric formulation is well tolerated with a sweet taste and has a favorable risk-benefit profile at 2 mg/kg/dose twice daily.[313]

Selective ET_A Receptor Antagonists

Sitaxsentan and ambrisentan are the two commercially available selective ETA receptor antagonists. In adult PAH patients with NYHA functional class II, III, or IV, sitaxsentan treatment improves WHO functional class and exercise capacity as assessed by a 6-mile walk (6MW) test.[319,320] In a double-blind study, ambrisentan was evaluated at four dosages (1, 2.5, 5, or 10 mg) once daily for 12 weeks followed by 12 weeks of open label ambrisentan.[321] Initial experience with ambrisentan in children suggests that treatment is safe with similar pharmacokinetics to those in adults.[322] In a study of pediatric patients with PAH, 15 of 38 patients were switched from bosentan to ambrisentan and the remaining 23 children were treated with ambrisentan as an add-on therapy due to disease progression. In both patients, mPAP significantly improved (transition patients −55 ± 18 vs. 45 ± 20 mm Hg, $n = 13$, $P = 0.04$, add-on −52 ± 17 vs. 45 ± 19 mm Hg, $n = 13$, $P = 0.03$) during follow-up. WHO functional class improved in 31% of patients. Ten patients (26%) had side effects associated with ambrisentan treatment, including nasal congestion, headache, and flushing. However, no patients had aminotransferase abnormalities and there were no deaths after initiation of ambrisentan during follow-up. In patients with Eisenmenger syndrome, ambrisentan was safe and associated with increased exercise capacity at short-term follow-up with patients maintaining functional class, SpO_2, and hemoglobin with no significant evidence of clinical deterioration at long-

term follow-up.[323] Ambrisentan use in children is increasing due to once-daily dosing, lack of drug interaction with PDE5 therapy, and decreased risk of elevated liver enzymes. Pediatric dosing is not available due to insufficient clinical data, but pediatric patients can be started on ambrisentan at 2.5 mg (<20 kg) or 5 mg (≥20 kg) and the dose can be titrated to 5–10 mg depending on the clinical response and disease progression. Ambrisentan was FDA approved in 2007 for PAH patients with functional class II and III symptoms. As a class, endothelin receptor antagonists have a potential for liver injury and teratogenicity. Monthly monitoring of liver function tests, a monthly pregnancy test in women of child-bearing potential, and a periodic hemoglobin measurement are required. Precautions regarding contraception and testicular atrophy are similar to bosentan.

Phosphodiesterase Type 5 Inhibitors

Type 5 phosphodiesterase (PDE5) is primarily responsible for degradation of cGMP to inactive metabolite GMP. PDE5 appears to be particularly abundant in pulmonary vessels. One way of augmenting the concentration of cGMP in pulmonary vessels is by inhibiting the activity of PDE5. PDE5 inhibitors, such as sildenafil and tadalafil, have antiproliferative, proapoptotic, and vasodilating effects on the pulmonary vasculature by increasing cGMP.[324] PDE5 inhibitors are administered orally and are well tolerated. Side effects include headache, flushing, dyspepsia, epistaxis, and erections in males. Vision abnormalities are dose related and rarely occur with therapeutic dosing, yet visual and hearing assessments should be considered in premature infants on PDE5 therapy.

Sildenafil

The FDA approved sildenafil in 2005 for the treatment of adult PAH at doses of 20 mg three times daily. Two small studies have shown that oral sildenafil improves hemodynamics and exercise capacity (6MW test) for up to 12 months at doses of 0.25 to 1 mg/kg four times daily[325] and improved oxyhemoglobin saturations and exercise tolerance in children with PAH without any side effects.[326] STARTS-1 is a multicenter trial of children randomized to low (10 mg), medium (10–40 mg), or high (20–80 mg) doses of sildenafil (ages: 1-17 years) for 16 weeks with PAH.[327] The doses of sildenafil were adjusted on the basis of body weight and steady state maximum concentration of sildenafil. Although the primary outcome of percent change in peak oxygen consumption (PVO_2) for the three sildenafil groups was only marginally significant, the improvement in exercise capacity, functional class, and hemodynamic improvements with the medium and high doses suggests efficacy of sildenafil at these doses.[327] The most frequent adverse events included headache, pyrexia upper respiratory tract infection, and diarrhea. In STARTS-2, sildenafil-treated patients continued STARTS-1 dosing and placebo-treated patients were randomized to one of the three sildenafil dose groups (n = 1234).[328] All children received sildenafil for ≥3 years from STARTS-1 baseline; 37 deaths were reported (26 on study treatment). Most patients who died (28/37) had idiopathic PAH (76% vs. 33%) and baseline functional class III/IV disease (38% vs. 15%); patients who died had worse baseline hemodynamics. K-M estimated that 3-year survival rates from the start of sildenafil were 94%, 93%, and 88% for patients randomized to low-, medium-, and high-dose sildenafil, respectively; 87%, 89%, and 80% were known to

be alive at 3 years. Hazard ratios for mortality were 3.95 (95% CI, 1.46–10.65) for high versus low and 1.92 (95% CI, 0.65–5.65) for medium versus low dose.[328] Although children randomized to higher compare with lower sildenafil doses had an unexplained increased mortality, all sildenafil dose groups displayed favorable survival for children with PAH. In 2012 the FDA released a strong warning against the chronic use of sildenafil for pediatric (ages 1 through 17) with PAH, citing that children taking high doses of Revatio (sildenafil) had a higher risk of death than children taking a low dose and low doses of Revatio are not effective in improving exercise ability. A consensus statement of experts strongly recommended avoiding high doses of sildenafil and adjusting the dosage to 10 mg three times daily (8–20 kg body weight) or 20 mg three times a day (>20 kg).[329] The current FDA review is not relevant regarding the short-term use of sildenafil in the critical care setting. Sildenafil is also useful to treat rebound PH in the settings of withdrawal from nitric oxide therapy,[330,331] management of postoperative pulmonary hypertensive crisis,[332] and treating pulmonary hypertension resulting from bronchopulmonary dysplasia.[333,334] For children <8 kg body weight, the dose of 0.25–1 mg/kg three times a day is recommended,[335] but it has been dosed four times a day in some centers. As sildenafil is metabolized by hepatic CYP-450, coadministration of sildenafil with CYP3A inducers or inhibitors such as ketoconazole or rifampin should be avoided.[276]

Tadalafil

Tadalafil is a phosphodiesterase-5 (PDE5) inhibitor that was approved by the FDA in 2009 for the treatment of PAH. Tadalafil has a greater affinity (10,000-fold) for PDE5 compared with the other PDE inhibitors and is long-acting with a half-life of 17.5 hours. In a controlled clinical study in patients with PAH, patients receiving tadalafil in a total daily dose of 40 mg had significant improvements in their 6MW distance and time to clinical worsening.[336] In a recent study, oral tadalafil (1 mg/kg once a day) was administered easily and tolerated well, and it improved mean pulmonary artery pressure in children with PAH, suggesting oral tadalafil may be more effective and safer than sildenafil in the treatment of PAH.[337] Patients were switched from sildenafil to tadalafil with no significant side effects and were shown to improve functional capacity and oxygen capacity better than sildenafil with fewer daily doses, suggesting that tadalafil may be the better drug.[338]

Combination Therapy

The goal of combination therapy is to maximize efficacy and minimize toxicity. The safety and efficacy of combination therapy in PAH are subjects of active investigation. As noted earlier, agents that inhibit degradation of cGMP (PDE5 inhibitors) may act synergistically with iNO. Similarly, inhibiting PDE3, a principal metabolizer of cAMP, might be expected to augment the response to PGI_2. Inhaled milrinone, either alone or in combination with inhaled PGI_2, selectively dilates the pulmonary vasculature without systemic effects in cardiac surgical patients with PH.[339] Inhaled iloprost has been studied in patients who remained symptomatic (NYHA functional class III or IV) while on stable bosentan therapy for at least 3 months.[340] After 12 weeks, the primary efficacy measure, postinhalation 6MW test improved significantly in the iloprost group, along with improvements in mean PAP and functional class. Sildenafil in patients who remained symptomatic on a stable

dose of epoprostenol for at least 3 months demonstrated an improvement in the 6MW test, mean PAP, and time to clinical worsening.[341] Oral bosentan and sildenafil in combination have been shown to be effective in the treatment of IPAH and PAH-CHD in children.[342] There is a mutual pharmacokinetic interaction between bosentan and sildenafil that may influence the dosage of each drug in a combination treatment. Bosentan decreases the maximum plasma concentration of sildenafil (C_{max}) by 55.4% on Day 16, whereas sildenafil increased bosentan C_{max} by 42.0%. Hence close monitoring is advisable with coadministration.[343] However, Bosentan and sildenafil in combination were well tolerated, with no serious adverse events reported. Side effects in pediatric PAH were more commonly reported in patients on combination therapy with an ERA and/or prostacyclin, likely due to a synergistic effect and commonly include flushing, diarrhea, dyspepsia, headache, and hyperactivity.[344]

Pulmonary Thromboendarterectomy

Patients with suspected PAH should undergo evaluation for chronic thromboembolic pulmonary hypertension. Chronic thromboembolic pulmonary hypertension (CTEPH) is a rare form of pulmonary hypertension that can lead to progressive right heart failure and death. CTEPH should be an important diagnostic consideration in symptomatic children with a known hypercoagulable state, a history of thromboembolism or venous catheter placement, and/or a diagnosis of pulmonary hypertension. The screening tool of choice is the perfusion scanning. If indicative of CTEPH, pulmonary angiography should be performed. Patients are considered to be candidates for surgery if they have surgically accessible disease and present an acceptable risk. Pulmonary thromboendarterectomy surgery in pediatric patients with CTEPH is well tolerated with improved postoperative hemodynamics, functional status, minimal postoperative complications, and low perioperative mortality, similar to that reported for adults with CTEPH, with the notable exception being a higher rate of rethrombosis in pediatric patients.[345] The surgery has to be performed at a center experienced in performing this procedure with excellent technical skills and support systems in place.

Atrial Septostomy

Despite advances in medical treatment for PAH, many patients experience progressive functional decline, largely from worsening right heart failure. Fortunately, it is uncommon to see patients in the pediatric age group in end-stage PAH compared with adults. In these patients, interventional and surgical options including atrial septostomy and lung or combined heart and lung transplantation should be considered. In patients with symptomatic cor-pulmonale secondary to pulmonary vascular disease, atrial septostomy can improve symptoms and may serve as a palliative bridge to heart and/or lung transplantation.[346,347] The procedure permits right-to-left shunting, decompresses the right heart, and increases left ventricular preload. Several case series have reported hemodynamic and clinical improvement following atrial septostomy.[346,347] Improved cardiac output appears to be the principal hemodynamic benefit. Improvements in NYHA functional class and 6MW test have also been reported.[348] The success rates for bridging patients to transplantation, with septostomy, ranges from 30% to 40%.[346,347] In a retrospective

study in children with IPAH, 19 underwent atrial septostomy at a mean age of 8.4 years.[349] There were no deaths, with improvement in syncope, WHO functional class, and echocardiographic assessment of right ventricular function.[349] Procedural mortality rate and complications are high and hence atrial septostomy has to be performed in experienced centers only. Currently, atrial septostomy is recommended for patients with severe PAH and intractable right heart failure despite maximal medical therapy, including optimized PAH specific agents and inotropes. The goals of the procedure are palliation and restoration and maintenance of clinical stability until a transplant can be performed.

Lung and Combined Heart/Lung Transplantation

Before PGI_2 became available as the long-term therapy, lung transplantation was the only option for survival for patients with severe pulmonary hypertension. Single-lung, double-lung, and heart-lung transplantation have all been advocated as the operation of choice in PAH. Transplantation is offered after maximal therapeutic effort with vasodilators and oxygen has been attempted and when the estimated 2-year survival is less than 50%.[350] Most centers now perform bilateral lung or heart-bilateral lung transplantation for PAH. IV PGI_2 has been used as a bridge to stabilize the patient until transplantation is accomplished. Extracorporeal membrane oxygenation (ECMO) is a safe and effective means of bridging well-selected patients with refractory respiratory failure to lung transplantation or return to their baseline condition, notwithstanding the considerable consumption of resources.[351] To date, more than 1800 lung transplants have been performed, most frequently in children >5 years of age.[352] Idiopathic PAH is the second most common indication for lung transplantation (LTx) in pediatric patients overall and the most common indication among children aged 1 to 5 years old. The 2013 IHSLT registry data of pediatric LTx performed between 1990 and 2011 reports a median survival of 4.9 years for pediatric patients. This observed survival is statistically similar to that of adult LTx recipients (4.9 years vs. 5.4 years). Like in adults, there has been a clear improvement in survival of 3.3 years among those transplanted between 1988 and 1999 versus median survival of 5.8 years in those transplanted in 2000 to 2011.[352] The most common causes of death following LTx include graft failure (first 30 days), non-CMV infection (1 month to 1 year), and bronchiolitis obliterans (after the first year). In a single-center study of LTx for IPAH, the median survival for those transplanted was 5.8 years, with 1- and 5-year survival rates of 95% and 61%, respectively. Compared with the transplanted group, children who died waiting had a significantly higher incidence of suprasystemic right heart pressures and hemoptysis.[353] As outcomes for infants listed for lung or heart/lung transplantation are similar to that of children, very young age should not be considered a contraindication to lung or heart/lung transplantation.[354] Earlier diagnosis and listing may decrease pretransplant mortality.[354] Even though the early outcome following lung transplantation has improved considerably, long-term complications, including infections, bronchiolitis obliterans, and complications of immunosuppression remain significant problems.[355] Aggressive medical therapy combined with early recognition of lung transplant candidates will improve quality of life and overall survival of these children.

Prognosis and Survival in PAH

Despite advances, vasodilators remain the mainstay in the management of PAH in children. Fig. 56.11 presents an overview of the complex management of PAH in children, with various options to choose at this time. The treatment algorithm is a minor modification with emphasis on initial diagnosis and management of these patients from the expert consensus document for pulmonary hypertension.[247] The goal of therapy should be to improve the quality of life and survival of these children with PAH. While most of the studies have been focusing on short-time end points such as 12 weeks' duration or 6MW test and long-term follow-up data on these patients are lacking. Although the therapies are evolving rapidly in the management of PAH, long-term experience with epoprostenol has suggested the importance of early follow-up because patients who remain in functional class III or IV despite therapy have poor outcomes and should be considered for lung transplant.[287] Data from the REVEAL registry suggest that the median age at diagnosis was 7 years. At diagnosis the mPAP and PVRI were 56 mm Hg and 17 WU/m^2, respectively, with a 5-year survival from diagnosis of 74% ± 6%. Increased survival from enrollment included the ability to respond to vasoreactivity testing and lower brain natriuretic peptide.[169] In a study comparing factors impacting survival at three major referral centers (NY, Denver, and Netherlands), diagnosis, WHO functional class, mPAP/mSAP, and PVRi were identified as independent predictors of outcome among center cohorts. Moreover, the treatment of PAH-targeted combination therapy during the study period was independently associated with transplant-free survival.[356] In a recent single-center study of 65 children with PAH, the 5-, 10- and 15-year survival rates were 96%, 92%, and 65%, respectively, and there was no significant correlation between outcome and immediate response to the vasodilators.[357]

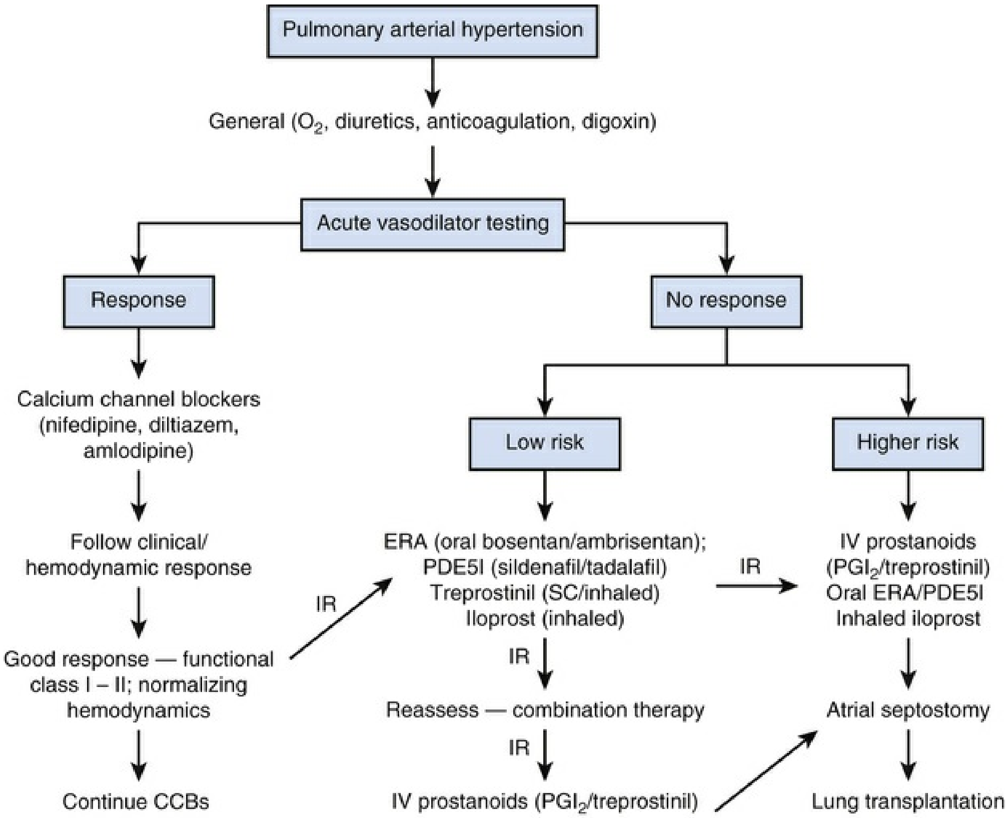

FIG. 56.11 Treatment algorithm for pulmonary arterial hypertension. See text for details. Diuretics are used in management of right heart failure. O_2 is recommended to maintain SpO_2 >90%. Calcium channel blockers (CCBs) are indicated for patients who have a positive acute vasodilator response. For patients who do not respond to acute vasodilator testing and are considered lower risk on the basis of clinical assessment, oral therapy with endothelial receptor antagonist (ERA) or phosphodiesterase 5 inhibitors (PDE5I), inhaled treprostinil, or iloprost would be the first line of therapy. For patients who are considered high risk on the basis of clinical assessment, continuous treatment with IV prostacyclin (PGI2) or treprostinil would be the first line of therapy recommended with or without oral ERA/PDE5I. Iloprost is a prostacyclin analog delivered as an aerosol. Combination therapy should be considered when patients are not responding adequately to initial monotherapy. Timing for lung transplantation and/or atrial septostomy is challenging and reserved for patients who progress despite optimal medical treatment. *IR,* incomplete response; *SC,* subcutaneous. (Modified from the Expert Consensus Document on Pulmonary Hypertension. McLaughlin VV, Archer SL, Badesch DB, et al. ACCF/AHA 2009 expert consensus document on pulmonary hypertension: a report of the American College of Cardiology Foundation Task Force on Expert Consensus Documents and the American Heart Association developed in collaboration with the American College of Chest Physicians; American Thoracic Society, Inc.; and the Pulmonary Hypertension Association. J Am Coll Cardiol. 2009;53:1573-1619.)

For clinical decision making in the treatment of these patients, it is important to be able to predict survival using prognostic factors.[358] In a systematic review and meta-analyses, WHO-functional class, (N-terminal pro-) brain natriuretic peptide, mean right atrial pressure, cardiac index, and acute vasodilator response were consistently reported prognostic factors for outcomes in pediatric PAH.[359] While echocardiography has been a pivotal screening test, the presence of any degree of

pericardial effusion has been proven to be a consistent predictor of mortality.[360] More recently, tricuspid annular plane systolic excursion (TAPSE) on echocardiography has been shown to be a robust measure of RV function and a powerful predictor of patient survival in PH.[361] TAPSE of less than 1.8 identifies patients with more advanced right ventricular dysfunction in patients with PH. Also these patients had reduced survival over a median follow-up of 19 months. Cardiac MRI accurately assesses size and function of the RV with a high degree of reproducibility. RV function is an important prognostic indicator in PAH, and MRI of poor RV function was found to be an independent predictor of mortality and treatment failure.[245]

Conclusions

Advances in the treatment of pulmonary hypertension in the past decade have improved survival of children with PAH. New clinical trials in children are helping to define optimal dosing of mono and combination therapy to avoid potential toxicities. Functional class has been evolving on the basis of child development, but optimal end points are still being defined. The biological variability and progressive nature of the disease in children make longer observations to therapy problematic. All this makes clinical investigations in children more difficult, but the potential rewards for having a significant impact on overall quality of life, as well as long-term survival, far outweigh the hurdles in developing newer management options for children.

CHAPTER 57

Mechanical Ventilation and Respiratory Care

Shekhar T. Venkataraman

PEARLS

- Modern pediatric respiratory care requires a major institutional commitment in resource allocation for state-of the-art management of the patient requiring mechanical ventilation.
- A team approach in which the roles and responsibilities of each of the team members (physicians, respiratory therapists, bedside nurses, and the family) are clearly defined and respected is required.
- Every team member must be abreast of the technologic advances in the design and implementation of mechanical ventilation.

Introduction

This chapter reviews the applied physiology relevant to gas exchange and lung mechanics, design and function of ventilators including a modern classification of the modes, guidelines for the use of mechanical ventilation based on pathophysiology, philosophy and practice of weaning, respiratory care adjuncts to mechanical ventilation, high-frequency ventilation, adverse effects of mechanical ventilation, and home respiratory care. The topic of noninvasive mechanical ventilation including negative pressure ventilation is covered elsewhere (see Chapter 58).

Applied Respiratory Physiology

Lung Volumes and Capacities

Air gets in, air gets out; oxygen is taken up, carbon dioxide is eliminated; this is the essence of breathing. Tidal volume is the volume of gas that is moved in and out of the lungs per breath and is normally 6 to 8 mL/kg for a spontaneous breath, regardless of age. Total lung capacity (TLC) is the volume of gas present in the lung

with maximal inflation (60–80 mL/kg). Vital capacity is the volume of gas that can be maximally expired from TLC (40–50 mL/kg). Functional residual capacity (FRC) is the volume of gas that is present in the lung at the end of a normal expiration. FRC results from the balance between forces that favor alveolar collapse and maintain alveolar inflation. The normal FRC is about 30 mL/kg. Residual volume is the volume of gas present in the lung at the end of a maximal expiratory effort. Closing volume refers to the volume of gas present in the lung at which small conducting airways begin to collapse. When FRC exceeds closing volume, the small airways and the alveoli remain open. On the other hand, when closing volume exceeds FRC, the small airways and alveoli tend to collapse. In infants and children younger than 6 years, the closing volume exceeds FRC. This explains the propensity for atelectasis in infants and young children. With development, FRC exceeds closing volume in children older than 6 years.

Physiology of Inflation and Deflation

Impedance to Lung Inflation

Thoracic structures impede lung inflation, and a certain amount of force is required to overcome this impedance. Elasticity of the lung and chest wall is a major factor that impedes lung inflation. Elastance is defined as the change in pressure for a unit change in volume. Compliance is the reciprocal of elastance. Lung compliance is defined as the change in lung volume for a unit change in transalveolar pressure (alveolar pressure minus the pleural pressure). Chest compliance is the change in thoracic cage volume produced by a unit change in transthoracic pressure (ambient pressure minus the pleural pressure). Total respiratory system compliance is the total change in lung volume (lung and chest) for a unit change in transrespiratory pressure (alveolar pressure minus the ambient pressure). Disease processes that result in an abnormal lung or chest wall compliance are given in Table 57.1. Specific lung compliance refers to lung compliance that is normalized to the lung volume or body weight (similar in children and adults). The pressure required to overcome compliance is:

$$P_{\text{Compliance}} = \text{Volume/Compliance or Volume} \times \text{Elastance}$$

Total respiratory system resistance is the second factor that impedes inflation and is defined as the change in transpulmonary pressure (proximal airway pressure minus the alveolar pressure) required to produce a unit flow of gas through the airways of the lung. Total resistance can be partitioned into airway resistance and frictional resistance to deformation of the lungs, chest wall, and abdominal contents.[1] In the infant, the airway resistance is equally distributed between the upper and lower airways. With increasing age, most of the airway resistance resides in the upper airways. Frictional resistance is also known as the *nonelastic viscous resistance.* In certain pathologic conditions, such as pulmonary edema, interstitial lung disease, and pulmonary fibrosis, frictional resistance may be increased. The pressure required to overcome this total resistance can be written as:

$$P_{\text{Total Resistance}} = P_{\text{Resistance}} + P_{\text{Frictional resistance}}$$
$$= \text{Total Respiratory Resistance} \times \text{Flow}$$

Inertance of the respiratory gas is another factor that impedes inflation, and the pressure required to overcome inertial forces of the gas is normally low and can be omitted.[1] Then, the total pressure (P_{tp}) required to inflate the lung can be mathematically expressed as follows, termed the "Equation of Motion":

$$P_{tp} = P_{\text{Compliance}} + P_{\text{Total Resistance}}$$

TABLE 57.1

Factors Associated With Decreased Total Respiratory Compliance

Decreased Lung Compliance
Surfactant deficiency or alteration
Respiratory distress of the newborn
Adult respiratory distress syndrome
Interstitial inflammation
Diffuse pneumonitis
Fibrosis
Pulmonary edema
Alveolar edema
Interstitial edema
Hyperinflation
Airway obstruction—both upper and lower
Excessive CPAP/PEEP or auto-PEEP
Atelectasis
Decreased Chest Compliance
Restrictive pleural disease
Pleural collection of air or fluid
Fibrosis
Increased intercostal muscle tone
Upper motor neuron disease
Drugs
Restrictive chest diseases
Deformations—kyphosis, scoliosis, or both
Ankylosis
Restrictive bandages
Diaphragmatic Restriction
Abdominal distention
Abdominal binding
Increased abdominal pressure—peritoneal dialysis, postlaparotomy, etc.

CPAP, continuous positive airway pressure; *PEEP*, positive end-expiratory pressure.

Concept of Time Constant

With a constant inflation pressure, it takes a finite amount of time to inflate the lung with a given volume of gas. The rate of inflation and deflation of the lung is approximately mono-exponential and is directly proportional to the compliance and the resistance. Time constant is calculated as the product of compliance and resistance. It takes one, three, and five time constants to cause a 63%, 95%, and a 99% change in lung volume, respectively (Fig. 57.1).[1] Normal expiration is passive because of the elastic recoil of the lung, which is attributable to alveolar surface tension and tissue elasticity. Surface tension is greatest at high lung volumes and lowest at FRC. Elastic recoil of the lung provides most of the force required to expel the gas from the lungs. Inspiratory and expiratory time constants may be different

because the inspiratory and expiratory resistances are different.

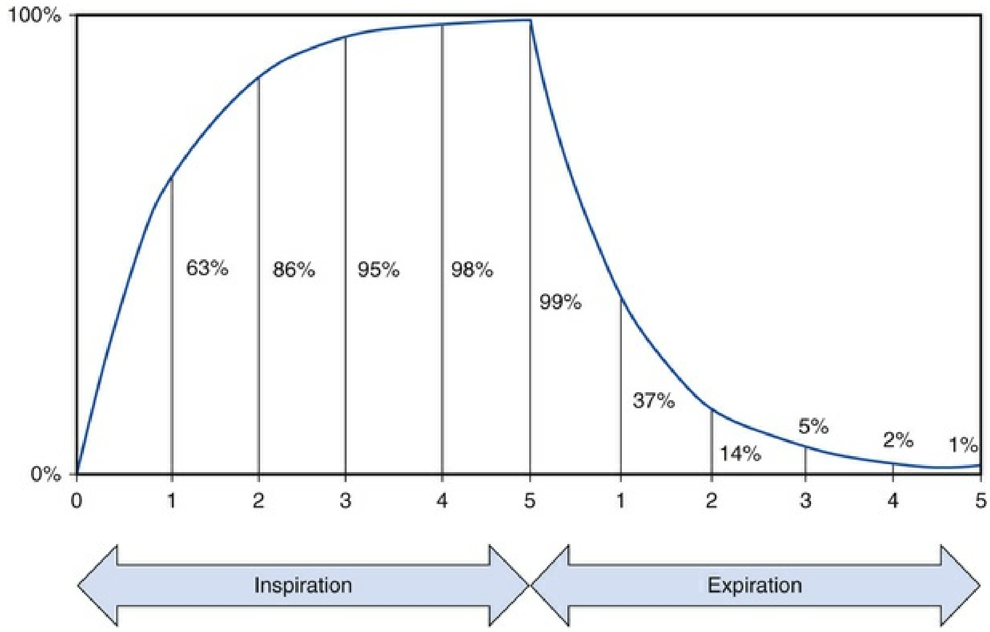

FIG. 57.1 Inspiratory and expiratory time constants. This graph shows the change in lung volume during inspiration and expiration by time constants. It takes 1, 2, 3, 4, and 5 time constants to cause a 63%, 86%, 95%, 98%, and 99% change in lung volume.

Work of Breathing

During normal breathing, the work of breathing is performed entirely by the inspiratory muscles (Fig. 57.2), and almost all of the work is performed during inspiration. Nearly half of the work of breathing during inspiration is dissipated as heat to overcome frictional resistance.[1] The remaining inspiratory work is stored as potential energy that is used to perform the expiratory work. Increased airway resistance and decreased chest and lung compliances would require a greater P_{tp} to inflate the lung to the same lung volume. These changes impose a greater workload on the respiratory muscles and increase the oxygen cost of breathing. When the oxygen supply-demand balance to the respiratory muscles is perturbed, respiratory failure may ensue because of muscle fatigue.

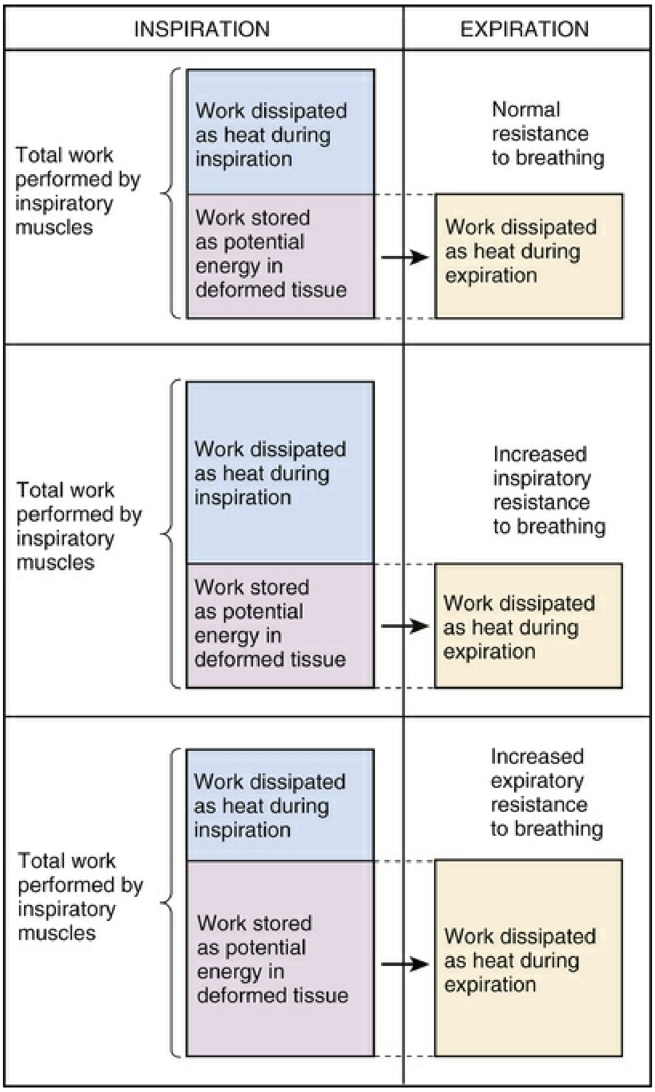

FIG. 57.2 Work of breathing of respiratory muscles. The area in each box represents the amount of work performed. The left side shows the total amount of work performed with normal resistance and increased inspiratory and expiratory resistances to breathing. (Reproduced with permission from Nunn JF. Applied Respiratory Physiology. 3rd ed. London: Butterworths; 1987.)

Determinants of Gas Exchange

The determinants of systemic arterial oxygenation are inspired oxygen concentration and tension, lung volume, cardiac output, ventilation-perfusion (V/Q) matching, and the magnitude of venous admixture or intrapulmonary shunting. Lung volumes increase during inspiration and fall during expiration. During expiration, the presence of alveolar surfactant prevents alveolar collapse. A critical opening pressure is required to maintain both the patency of the terminal airways and alveolar volume. When the airway pressure is below the critical opening pressure, the terminal airway closes and the alveoli collapse because of continued absorption of gases into the bloodstream. Surfactant deficiency, loss, or alteration promotes alveolar collapse and increases the critical opening pressure. In parenchymal lung disease, which is characterized by an increased critical closing pressure, alveoli

collapse during expiration if the airway pressures cannot be maintained above the critical opening pressure. Alveolar collapse leads to inadequate oxygenation due to increased intrapulmonary shunting resulting from (V/Q) mismatch.

The determinants of systemic arterial carbon dioxide ($PaCO_2$) include the tidal volume and the ventilator rate. $PaCO_2$ reflects the balance between metabolic production of CO_2 and its elimination. Decreased CO_2 elimination usually results from decreased central drive, lower airway obstruction, parenchymal disease, and muscle weakness. Inadequate ventilation causes CO_2 retention when it becomes insufficient to clear metabolic CO_2 production at a normal $PaCO_2$ (Table 57.2). Increased metabolic production of carbon dioxide usually results from hypermetabolic states or excessive caloric intake, especially high-carbohydrate alimentation.

TABLE 57.2

Causes of Ventilatory Pump Failure

Decreased Respiratory Muscle Capacity
Decreased respiratory center output (central nervous system disorders)
Phrenic nerve injury
Decreased muscle strength or endurance
Malnutrition
Prolonged neuromuscular blockade
Muscle fatigue
Electrolyte abnormalities
Increased Respiratory Muscle Load
Increased work of breathing
Hyperinflation
Lower airway obstruction
Decreased respiratory system compliance
Increased ventilatory requirements
Increased carbon dioxide production (eg, excessive carbohydrate intake)
Increased dead space
Hypercatabolic states (eg, sepsis)

Indications for Mechanical Ventilation

Respiratory Failure

The primary indication for institution of assisted ventilation is respiratory failure. Respiratory failure is generally defined as the presence of (1) inadequate oxygenation, (2) inadequate ventilation, or (3) both. Apnea or respiratory arrest is an extreme form of respiratory failure, and prolonged apnea is usually an indication for immediate mechanical ventilation. *Inadequate oxygenation,* objectively, is defined as partial pressure of arterial oxygen (PaO_2) less than 60 torr or an arterial hemoglobin oxygen saturation of less than 90% in room air. Oxygenation can also be expressed as the ratio of PaO_2 to fractional concentration of oxygen in inspired gas (FiO_2). *Inadequate oxygenation* can also be defined as a PaO_2-FiO_2 ratio of less than 300. Other indices include an alveolar-to-arterial oxygen gradient of more than 300 torr with a FiO_2 of 1.0. Inadequate oxygenation due to intrapulmonary shunting can be overcome with the addition of increased inspired oxygen concentration, provided the magnitude of the shunt is less than 15% (Fig. 57.3). Intrapulmonary shunt can be

decreased by with the re-expansion of collapsed alveoli or with the decrease in the fraction of pulmonary blood flow going to the collapsed/consolidated alveolar segments. *Inadequate ventilation* is defined as a $PaCO_2$ greater than 45 torr with an arterial pH of less than 7.35 in the absence of chronic hypercapnia. Acute-on-chronic ventilatory failure is defined as a change in $PaCO_2$ of at least 20 torr with a corresponding decrease in arterial pH. Impending respiratory failure, characterized by rapidly rising $PaCO_2$, progressive respiratory distress, $PaCO_2$ out of proportion to the respiratory effort, or fatigue of respiratory muscles, is a relative indication for mechanical ventilation. Intubation and institution of mechanical ventilation in impending respiratory failure are likely to be more controlled than when full-blown respiratory failure develops. Therefore in critically ill children, establishing mechanical ventilation before respiratory failure develops is preferable. Chronic respiratory failure is defined as requirement for mechanical ventilation for more than 28 days. Children with chronic lung disease often fail to grow despite adequate caloric intake. In these patients, mechanical ventilation may decrease the work of breathing enough to allow the child to grow.

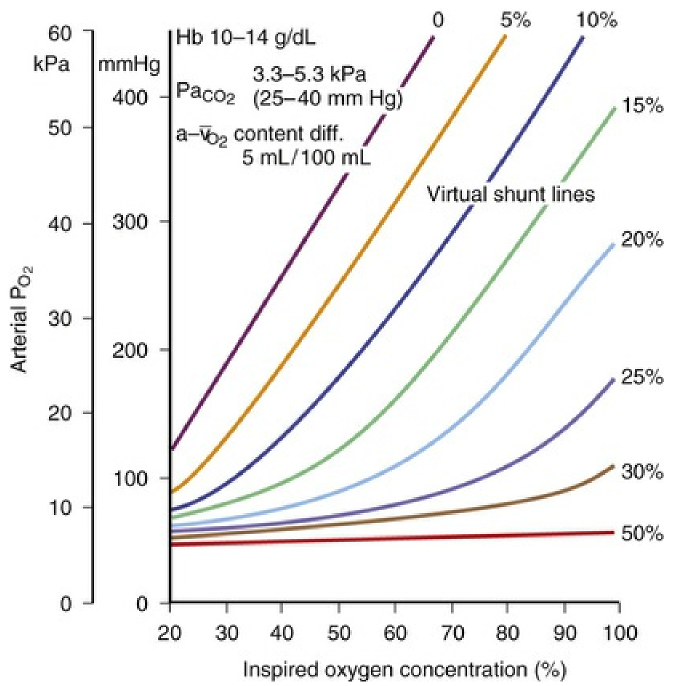

FIG. 57.3 Iso-shunt diagram. This shows the relationship among the magnitude of intrapulmonary shunt, the inspired oxygen concentration, and the arterial oxygen tension for a hypothetical patient. (Reproduced with permission from JF Nunn. Applied Respiratory Physiology. 3rd. London: Butterworths; 1987.)

Cardiovascular Dysfunction

Moderate to severe cardiovascular dysfunction is another major indication for mechanical ventilation. The cardiovascular and respiratory systems must act in concert to maintain adequate gas exchange and thereby meet the metabolic demands of the whole body. Therefore the two systems cannot be functionally divorced from

each other. Cardiovascular dysfunction can result in a decrease in respiratory reserve and an increase in respiratory work and may ultimately result in respiratory failure. Positive pressure ventilation decreases lactic acid production by respiratory muscles during circulatory shock, and withdrawal of ventilatory support results in a marked increase in cardiac work with poor cardiac reserve.[2,3]

Neurologic and Neuromuscular Disorders

Acute neurologic disorders may require mechanical ventilation for many reasons. First, neurologic disorders may result in decreased ventilatory drive and therefore result in acute hypercapnia. Second, loss of airway protective reflexes may require an artificial airway for maintaining airway integrity and for providing an access for suctioning pooled secretions. Third, mechanical ventilation may be instituted to deliberately cause hyperventilation in disorders associated with intracranial hypertension to produce hypocapnia and respiratory alkalosis. Fourth, certain acute neuromuscular disorders such as Guillain-Barré syndrome, transverse myelitis, botulism, and drugs may result in decreased ventilatory effort because of muscle weakness and may result in hypoventilation and hypercarbia. Mechanical ventilation is usually instituted under these circumstances until the patient recovers from the primary disorder. Mechanical ventilation is also instituted for various chronic neuromuscular disorders such as muscular dystrophy and for permanent neurologic disorders such as spinal cord transection for prolonged home ventilator support.

Design and Functional Characteristics of Ventilators

A detailed review of the physical characteristics and functional design of ventilators is beyond the scope of this chapter, and the reader is referred to several excellent reviews on this subject.[4-16] In 1991, Chatburn proposed a new system for understanding the design of mechanical ventilators.[7] Since the initial publication in 1991, this classification has been subsequently updated and revised.[8-15] Most recently, Chatburn et al.[16] published fundamental maxims that describe the taxonomy of mechanical ventilation. The following is a summary that incorporates Chatburn's classification and taxonomy.[7-16]

Ventilator as a Machine

The concept is a simple one—a ventilator is simply a machine that performs external work.[6] This requires energy to be applied to the device, which is then altered, transmitted, and directed in a predetermined manner to perform the work of breathing. This work can either replace the patient's work of breathing completely or partially or augment a patient's breathing efforts. Therefore a ventilator is a mechanical device that is used to move gas into the lungs by increasing P_{tp}. Positive pressure ventilators create P_{tp} by raising the airway pressure (Paw) above the intrapleural pressure (P_{pl}), whereas negative pressure ventilators create P_{tp} by decreasing P_{pl} below Paw.

Classification of Ventilators

The scheme to classify mechanical ventilators is shown in Table 57.3. All ventilators include an input power, a drive system, a control system, a cycling mechanism, and a system to provide positive end-expiratory pressure (PEEP).[4-12] The accessories include a heated humidifier and an oxygen blender. The input power provides the energy to operate the ventilator and is usually electric or pneumatic. The drive system provides the force required to generate a gas flow. For gas flow to be provided, a pressure gradient needs to be created between the ventilator and the lungs. This is most commonly accomplished with compressed gases at high pressures from wall outlets or cylinders or a small compressor designed to be used with individual ventilators. In this scheme, the ventilator acts only to modulate the flow of gas and will not function if the external source of gas fails. Alternatively, some ventilators have a built-in compressor such as a piston and cylinder or a system of bellows, or a rotating vane. A ventilator that has an internal compressor does not need an external source of gas to inflate the lung.

TABLE 57.3

Outline of Ventilator Classification System

I. Input
A. Electric
1. AC
2. DC (battery)
B. Pneumatic
II. Power Conversion and Transmission (drive mechanism)
A. Compressor
1. External
2. Internal
B. Motor and linkage
1. Electric motor/rotating crank and piston rod
2. Electric motor/rack and pinion
3. Electric motor/direct
4. Compressed gas/direct
C. Output control valves
1. Electromagnetic poppet valve
2. Pneumatic poppet valve
3. Electromagnetic proportional valve
4. Pneumatic diaphragm
III. Control Scheme
A. Control circuit
1. Mechanical
2. Pneumatic
3. Fluidic
4. Electric
5. Electronic
B. Control variables and waveforms
1. Pressure
2. Volume
3. Flow
4. Time
C. Phase variables
1. Trigger variable
2. Limit variable
3. Cycle variable
4. Baseline variable
D. Modes of ventilation and conditional variables
IV. Output
A. Pressure
1. Rectangular
2. Exponential
3. Sinusoidal

4. Oscillating
B. Volume
1. Ramp
2. Sinusoidal
C. Flow
1. Rectangular
2. Ramp: (a) ascending ramp, (b) descending ramp
3. Sinusoidal
D. Effects of the patient circuit
V. Alarm Systems
A. Input power alarms
1. Loss of electric power
2. Loss of pneumatic power
B. Control circuit alarms
1. General systems failure (ventilator-inoperative)
2. Incompatible ventilator settings
3. Inverse I : E ratio
C. Output alarms
1. Pressure
2. Volume
3. Flow
4. Time
(a) high/low ventilatory frequency
(b) high/low inspiratory time
(c) high/low expiratory time
5. Inspired gas
a) high/low inspired gas temperature
b) high/low FiO_2

FiO_2, fractional concentration of oxygen in inspired gas; *I : E*, inspiratory-to-expiratory time ratio.

Reproduced from Chatburn RL. Classification of Mechanical Ventilators, Respiratory Care Equipment. Philadelphia: JB Lippincott; 1995.

The pressure generated within the ventilator can be thought of as the driving pressure that forces the gas into the lungs through the conducting system involving the ventilator circuit and the patient's airways. During mechanical ventilation, for a single breath, P_{tp} may be generated either by the ventilator or a spontaneous breath or a combination of both. Therefore the equation of motion can be reexpressed as:

$$P_{tp} = P_{mus} + P_{vent} = (\text{Volume} \times \text{Elastance}) + (\text{Total Resistance} \times \text{Flow})$$

where P_{mus} is the pressure exerted by the respiratory muscles and P_{vent} is the pressure exerted by the ventilator.

Compliance and resistance are assumed to remain constant during lung inflation and are called *parameters.* Pressure, volume, and flow in the respiratory system change with time and are therefore referred to as *variables.* Fig. 57.4 shows the classification scheme that is based on the equation of motion.

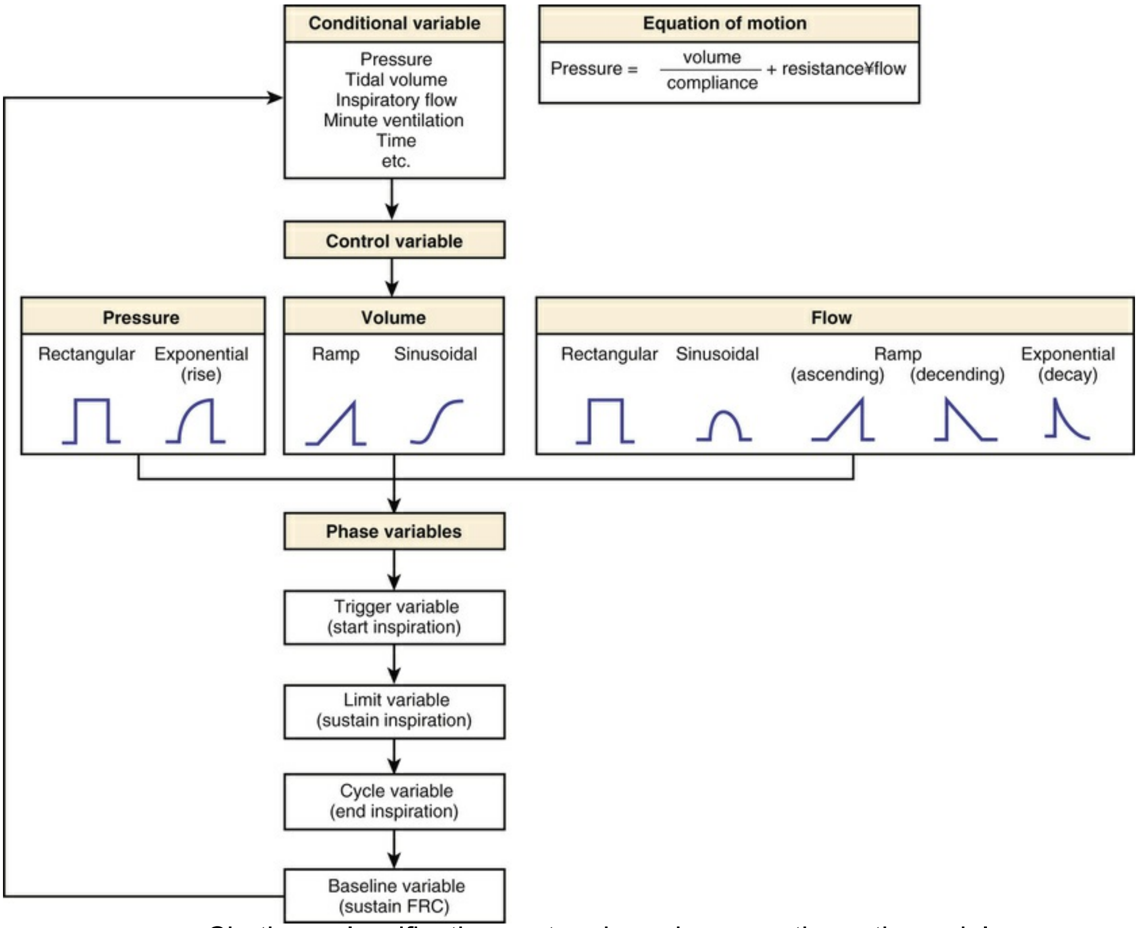

FIG. 57.4 Chatburn classification system based on a mathematic model known as the equation of motion for the respiratory system. This model indicates that during inspiration the ventilator is able to directly control one and only one variable at a time (eg, pressure, volume, or flow). Some common waveforms provided by current ventilators are shown for each control variable. Pressure, volume, flow, and time are also used as phase variables that determine the parameters of each ventilatory cycle (eg, trigger sensitivity, peak inspiratory flow rate or pressure, inspiratory time, baseline pressure). (Reproduced with permission from Chatburn RL. Classification of Mechanical Ventilators, Respiratory Care Equipment. Philadelphia: JB Lippincott; 1995.)

A ventilator can also be viewed as a form of mechanical controller that "controls" either pressure (in a pressure generator) or flow (in a flow generator). A pressure generator is a ventilator that generates a fixed pattern of pressure within the ventilator and at the mouth, regardless of the lung conditions, whereas the flow waveform is free to vary.[4,5] This occurs when the generated pressure is low (generally between 20 and 50 cms H_2O), which results in a high initial flow rate that decays to zero as the alveolar pressure approaches the generated pressure.[4,5] The generated pressure can be constant, nonconstant, increasing, or decreasing. The Hand-E-Vent (Ohio Medical Products), Bird Asthmatik (Bird Corporation), Bennett PR-1, and Bennett PR-2 ventilators are examples of pressure generators. A flow generator is a ventilator that generates a high driving pressure (3–50 psig corresponding to 200–3500 cm H_2O) and controls the inspiratory flow of gas into the patient by interposing a high series resistance system between the generated pressure and the patient. The flow generated may be constant, nonconstant,

increasing, or decreasing.[4,5]

Patterns of Gas Flow

The pattern of gas flow from the ventilator to the patient depends on the driving mechanism and the driving pressure in the ventilator. Four distinct flow patterns can be recognized: (1) a constant flow, (2) a decelerating flow, 3) an accelerating flow, and (4) a sinusoidal or sine-wave flow (Figs. 57.5–57.7). A constant inspiratory flow is generated when the driving pressure is high (eg, 50 psig) relative to the airway pressure. The drive mechanism is usually a high-pressure gas system (compressed air or oxygen at 10–50 psig). The driving force generally exceeds 1000 cm H_2O and is many times higher than the typical proximal airway pressure required to inflate the lungs. An adjustable resistance controls the pressure and flow to the proximal airway. The airway pressure and lung volume increase linearly until inspiration is terminated. Constant flow can also be generated by a linear-driven piston, which moves at a constant rate of speed during inspiration. A decelerating inspiratory flow is created when the driving pressure is relatively low (<60 cm H_2O). In this case, a pressure-reducing valve controls the driving pressure to the desired level. As the airway pressure and lung volume increase during inspiration, the pressure gradient between the drive mechanism and proximal airway decreases. Consequently, as inspiration progresses, the inspiratory flow from the ventilator decreases and finally stops at the end of inspiration. A sine-wave or sinusoidal inspiratory flow is created when the drive mechanism is a rotary wheel–driven piston. As the rotary wheel turns, the piston is moved to and fro in the cylinder in an accelerating and then a decelerating fashion. The inspiratory flow produced also has a similar profile. The notion that one specific flow pattern is more beneficial than the others is controversial. A detailed description of this topic is beyond the scope of this chapter, and the reader is referred to several excellent reviews.[4-12] Ventilators can also be classified as a single-circuit or a double-circuit device. A single-circuit device refers to a ventilator in which the gases go directly from the drive mechanism to the patient. On the other hand, a double-circuit device refers to a system in which the drive mechanism is used to compress another system that then delivers the tidal volume.[4-12]

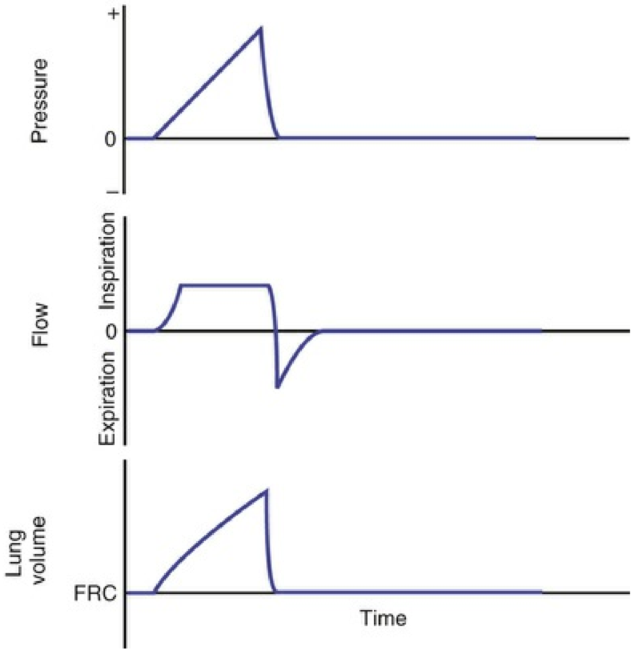

FIG. 57.5 Constant inspiratory flow. The flow quickly reaches a plateau and remains constant throughout the inspiratory phase. The airway pressure and lung volume increase relatively linearly. (Reproduced with permission from Kirby RR, Smith RA, Desautels DA. Mechanical Ventilation. New York: Churchill Livingstone; 1985.)

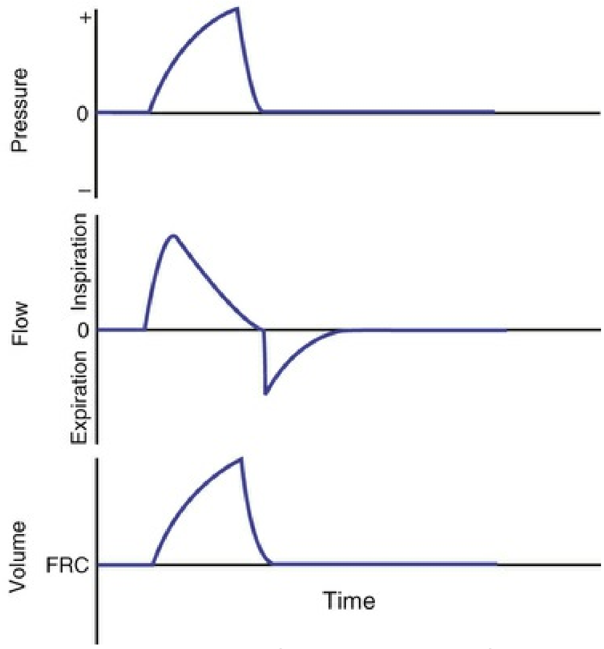

FIG. 57.6 Decelerating inspiratory flow. Inspiratory flow is maximal early in inspiration and gradually falls to zero at the end of inspiration. The airway pressure and lung volume rise exponentially. (Reproduced with permission from Kirby RR, Smith RA, Desautels DA. Mechanical Ventilation. New York: Churchill Livingstone; 1985.)

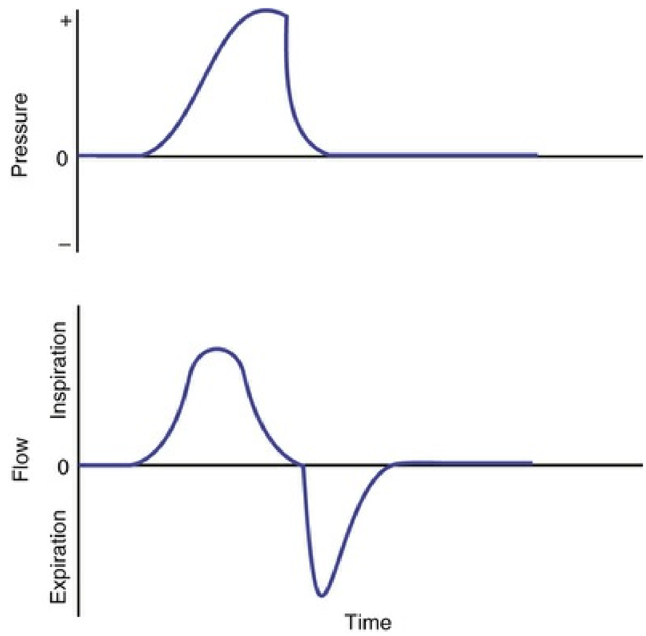

FIG. 57.7 Sinusoidal or "sine-wave" inspiratory flow. Inspiratory flow increases gradually and then falls gradually to zero. The airway pressure and lung volume increase in an S-shaped fashion. (Reproduced with permission from Kirby RR, Smith RA, Desautels DA. Mechanical Ventilation. New York: Churchill Livingstone; 1985.)

Modes of Ventilation

The section below is a summary of several excellent articles.[7-16] A mode of ventilation can be defined by a predetermined pattern of patient-ventilator interaction that has three components. They are (1) the ventilator breath control variable, (2) the breath sequence, and (3) the targeting scheme.

Ventilator Breath Control Variable

A breath is defined as one cycle of positive flow (inspiration) and negative flow (expiration) defined in terms of the flowtime curve.[16] Inspiratory time is defined as the period from the start of positive flow to the start of negative flow. Expiratory time is defined as the period from the start of negative flow to the start of positive flow. Total cycle time is the sum of inspiratory and expiratory times and is equal to the inverse of breathing frequency. The inspiratory-expiratory (I : E) ratio is defined as the ratio of inspiratory time to expiratory time. Percent inspiratory time (also called the *duty cycle*) is defined as the ratio of inspiratory time to total cycle time. The tidal volume (VT) is the integral of flow with respect to time. For constant flow inspiration, this simply reduces to the product of flow and inspiratory time.[16]

An unassisted breath is defined as one in which the ventilator provides the flow rate required by the patient's efforts, and the transrespiratory system pressure stays nearly constant throughout the breath.[16] Breaths occurring during continuous positive airway pressure (CPAP) are an example of unassisted breaths. An assisted breath is defined as one in which the ventilator performs some or all of the work of breathing. A fully supported breath is one in which the ventilator performs all of the mechanical work of inspiration (eg, drug-induced neuromuscular blockade) when

the respiratory muscles are inactive. In a fully supported breath, a ventilator assists breathing using either pressure control or volume control based on the equation of motion for the respiratory system.

It is important to understand that the term *volume control* means that the volume and inspiratory flow are predetermined. Only when both the parameters are preset can it be referred to as *volume control.* For example, if the tidal volume is preset but the ventilator is allowed to change the flow during inspiration, it would not be a volume-controlled breath. Similarly, if the inspiratory flow is preset but the volume delivered is dependent on the inspiratory pressure and/or the respiratory mechanics, then it cannot be referred to as volume control. It is important to understand that the term *volume control* is used as a standard term based on the taxonomy and does not refer to a manufacturer's mode.[16] Similarly, in pressure control, inspiratory pressure as a function of time is predetermined, which means presetting a particular pressure waveform or an inspiratory pressure proportional to the patient's effort (such as with neutrally adjusted ventilator assist [NAVA]). In pressure control, the flow and volume depend on the compliance and resistance of the respiratory system.[16] Again, pressure control does not refer to a specific manufacturer's mode. Time control is a category of ventilator modes in which the flow, volume, and pressure during inspiration depend on the mechanics of the respiratory system. High-frequency oscillatory ventilation (HFOV) and high-frequency percussive ventilation are examples of time control.[16]

Breath Sequence

Phases of a Breath

Trigger is a signal that starts inspiration. Time, pressure, flow, minimum minute ventilation, apnea interval, and electrical signals are used as inspiratory triggers. Cycling refers to the termination of inspiration and start of expiration. Inspiratory time, pressure, volume, flow, and electrical signals are used as cycling signals.[16] All ventilators are equipped with mechanisms to provide four basic functions: (1) inflate the lungs, (2) terminate lung inflation, (3) allow lungs to empty, and (4) start lung inflation.[7,8,10,11,16] The ventilator performs these functions through four phases: (1) the inspiratory phase, (2) the changeover from the inspiratory to the expiratory phase, (3) the expiratory phase, and (4) the changeover from the expiratory phase to the inspiratory phase.

Classification of Breaths

The criteria used to start (trigger) and stop (cycle) inspiration are used to classify breaths. Both triggering and cycling events can be initiated by either the ventilator or the patient. When inspiratory flow starts with a ventilator-generated signal, it is referred to as *ventilator triggering* and is independent of a patient-initiated signal. Similarly, when inspiration starts on a patient-generated signal, it is referred to as patient triggering and is independent of a ventilator-generated signal. Ventilator cycling refers to ending inspiration based on signals from the ventilator independent of signals based on patient factors. Time cycling is a common criterion and refers to the time that has elapsed from the start of inspiration and is breath-to-breath. Patient cycling occurs when a signal based on the patient's respiratory mechanics, which

affects the equation of motion, reaches a threshold value. For example, in flow cycling, which is a form of patient cycling, the inspiratory flow decays to the threshold value dependent on the patient's respiratory mechanics.[16]

Spontaneous Versus Mandatory Breaths

When the start and end of a breath are determined by the patient, it is referred to as a *spontaneous breath*.[16] This means that a spontaneous breath is both patient triggered and patient cycled and is independent of any ventilator settings. A spontaneous breath may be unassisted or assisted. An unassisted spontaneous breath refers to a breath where the patient determines both the timing and size of the breath. Normal breathing is unassisted spontaneous breathing. T-piece breathing or breaths during CPAP are also examples of unassisted spontaneous breathing.[16] The size of the breath is determined solely by the effort of the patient with no additional help from the ventilator. An assisted spontaneous breath refers to a breath where the ventilator does some of the inspiratory work indicated by an increase in airway pressure above the baseline. For an assisted breath, the patient must initiate a breath, and then the ventilator is triggered to provide a positive pressure breath. The trigger can be either pressure or flow. With an assisted spontaneous breath, the ventilator contributes to the size of the breath but it is important to understand that the patient determines the timing of the breath. Pressure-supported breath is an example of an assisted spontaneous breath. A mandatory breath is one in which the start or end of inspiration (or both) is determined by the ventilator, independent of the patient. The inspiratory time is not under the control of the patient. A mandatory breath may occur during a spontaneous breath (eg, high-frequency jet ventilation).[16] A spontaneous breath may occur during a mandatory breath (eg, airway pressure release ventilation). The criteria for determining the phase variables during a mechanical breath are shown in Fig. 57.8.

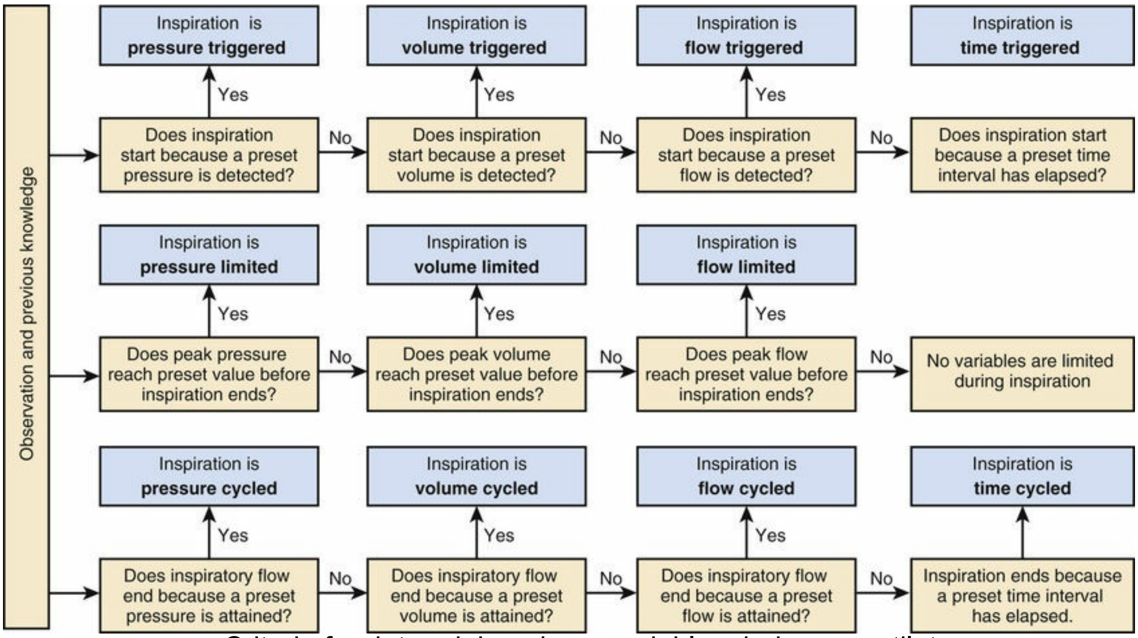

FIG. 57.8 Criteria for determining phase variables during a ventilator-assisted breath. (Reproduced from Chatburn RL. Classification of Mechanical Ventilators, Respiratory

Care Equipment. Philadelphia: JB Lippincott; 1995.)

Breath Sequences

Ventilators deliver three basic breath sequences: (1) continuous mandatory ventilation (CMV), (2) intermittent mandatory ventilation (IMV), and (3) continuous spontaneous ventilation (CSV).[8,10,11,16] CMV refers to a breath sequence when all the breaths are mandatory. Even if there is a patient-triggered signal, it will result in a mandatory breath. During CMV, spontaneous breaths are not permitted or do not occur between mandatory breaths. If the patient is breathing spontaneously during CMV, each spontaneous breath may trigger a mandatory breath. Assist-control refers to a mode of ventilation when a patient receives a combination of ventilator-initiated and patient-initiated mandatory breaths. The total number of mechanical breaths will be the sum of the preset frequency of ventilator breaths and the number of patient-triggered breaths. When all minute ventilation is provided by the ventilator, it is referred to as *total ventilatory support.* Total ventilatory support is provided when the patient does not take any spontaneous efforts because of a primary disease process (eg, quadriplegia, muscle disease), pharmacologic therapy (eg, induced neuromuscular blockade), or suppression of spontaneous breathing efforts (eg, hyperventilation). Spontaneous efforts are used only for triggering (assist-control). Total ventilatory support is provided entirely by CMV (Fig. 57.9).

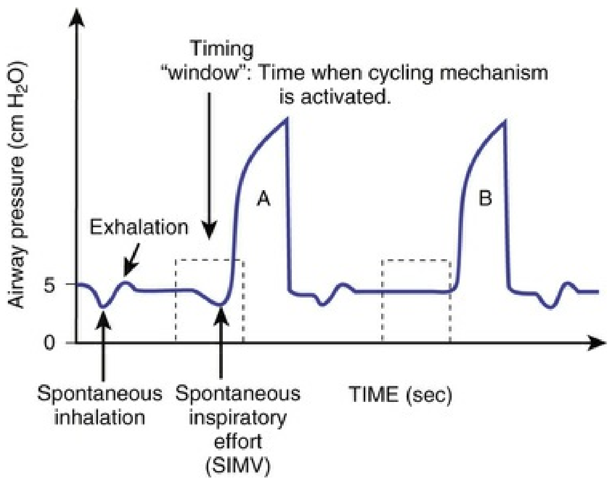

FIG. 57.9 Synchronized intermittent mandatory ventilation. At set intervals, the ventilator's timing circuit becomes activated and a timing "window" appears *(dotted line)*. If the patient initiates a breath in the timing window, then the ventilator will deliver a mandatory breath. If no spontaneous effort occurs, then the ventilator will deliver a mandatory breath a fixed time after the timing window. (Reproduced with permission from Kirby RR, Smith RA, Desautels DA. Mechanical Ventilation. New York: Churchill Livingstone; 1985.)

Intermittent Mandatory Ventilation

IMV refers to a breath sequence in which spontaneous breaths occur between mandatory breaths. The concept of IMV where spontaneous breathing occurred with a preset mechanical ventilator rate was first developed by Kirby et al.[17] in 1971 with

the use of a continuous flow circuit in the management of respiratory distress syndrome of the neonate. The total ventilatory support time and duration of weaning were significantly reduced in infants using IMV compared with CMV.[18,19] IMV was later introduced as a mode by Downs et al.[20] in 1973 to describe a mode of ventilation that allowed the patient to breathe spontaneously with a preset ventilator rate. The total minute ventilation is due to a combination of mandatory mechanical breaths and spontaneous breaths. There are three forms of IMV. In the first, mandatory breaths are always delivered at the set frequency. Two systems are currently available to deliver this form of IMV: One uses continuous flow, and the other uses a demand valve. These breaths may or may not be synchronized. When IMV is synchronized to the patient's inspiratory efforts, it is referred to as *synchronized IMV* (SIMV) (Fig. 57.11). The ventilator accomplishes this by creating a timing window just before the next mandatory breath is scheduled to be delivered. If the patient takes a spontaneous breath in this timing window and the ventilator senses this breath on the basis of the trigger sensitivity, then the mandatory breath is synchronized with the patient's effort. Each time a synchronized breath is delivered, the machine recomputes the time required to deliver the next mandatory breath. In SIMV, the total number of mandatory breaths will only be equal to the preset frequency of mandatory breaths. SIMV breaths can be either volume regulated or pressure limited. If a synchronization window is used, the ventilatory period of the previous mandatory breath may actually be shorter than the set period. In some ventilators, the next mandatory breath may be longer to maintain the set mandatory breathing frequency. In the second type of IMV, mandatory breaths are delivered only when the spontaneous breathing rate falls below a threshold (set individually for each patient). If the spontaneous rate is above the threshold, then all the breaths are assisted spontaneous breaths. But when the spontaneous rate falls below the set frequency, the breath sequence becomes IMV. The IMV rate is often referred to as a "backup rate." In the third form of IMV, when the spontaneous minute ventilation drops below a threshold, mandatory breaths are delivered to maintain the minimum minute ventilation (Fig. 57.10).

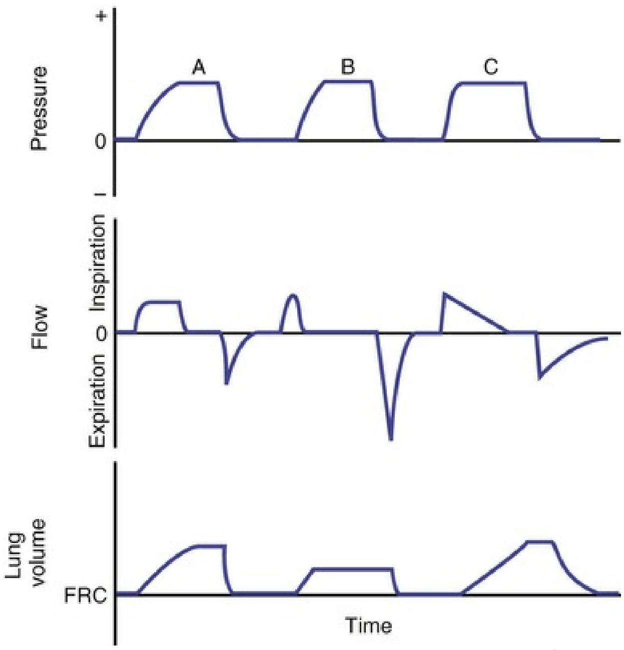

FIG. 57.11 Pressure-control ventilation. Inspiratory flow pattern is constant. Airway pressure and lung volume rise relatively linearly. The airway pressure reaches a preset pressure limit and does not change throughout inspiration. Lung volume follows the time course of the pressure curve with a slight lag. *(A)* Normal lung. *(B)* Lung with decreased compliance. *(C)* Lung with increased resistance. With decreased compliance the tidal volume delivered is decreased. With increased resistance, it takes longer to deliver the tidal volume. Ventilatory Pattern

A ventilatory pattern is a sequence of breaths (CMV, IMV, or CSV) with a designated control variable (volume control [VC] or pressure control [PC]). Thus there are six theoretically possible ventilatory patterns based on three breath sequences and two control variables. These are VC-CMV, PC-CMV, VC-IMV, PC-IMV, VS-CSV, and PC-CSV.[16] The VC-CSV combination is not possible because volume control implies ventilator cycling (time or volume) and therefore, by definition, is a mandatory breath. Thus we are left with five ventilatory patterns (Table 57.4).[16] These five ventilatory patterns are what are available in what would be termed "conventional ventilators." Time can also be a control variable so that both CMV and IMV are possible time control ventilatory patterns such as in high-frequency oscillatory ventilation (HFOV) or high-frequency percussive ventilation. Only one ventilatory pattern can be present in a mode of ventilation. The ventilatory pattern can be used as a mode classification system.[16]

TABLE 57.4

Breathing Patterns

Breath-Control Variable	Breath Sequence	Acronym
Volume	Continuous mandatory ventilation	VC-CMV
	Intermittent mandatory ventilation	VC-IMV

Pressure	Continuous mandatory ventilation	PC-CMV
	Intermittent mandatory ventilation	PC-IMV
	Continuous spontaneous ventilation	PC-CSV

Targeting Schemes

The relationship between operator inputs to ventilator outputs to achieve a specific ventilator pattern is termed a "targeting scheme" and is usually modeled in the form of a feedback control system. A target can be defined as a predetermined goal of the ventilator output. Targets can be set either within breaths or between breaths. Within-breath targets or parameters relate to pressure, flow, and volume waveforms. Between-breath targets, mainly used within advanced targeting schemes, may be set to modify the within-breath targets and/or the overall ventilatory pattern (between-breath targets).[16]

There are currently seven basic targeting schemes: (1) set-point targeting, (2) dual targeting, (3) biovariable targeting, (4) servo targeting, (5) adaptive targeting, (6) optimal targeting, and (7) intelligent targeting. In set-point targeting, the operator sets all of the parameters of the waveform (pressure or volume/flow). Dual targeting refers to a scheme in which the ventilator is allowed to switch between pressure and volume control. When the ventilator randomly sets the inspiratory pressure or the tidal volume to mimic the variability seen with normal breathing, it is referred to as biovariable targeting. Servo targeting allows the ventilator output to be automatically adjusted to a varying input. In adaptive targeting, the ventilator automatically sets one target (pressure in a breath) to achieve another (average tidal volume over several breaths). When a performance characteristic (eg, work rate of breathing) is minimized or maximized, by automatically adjusting the ventilatory pattern, it is referred to as optimal targeting. In the recent article on the taxonomy, Chatburn et al.[16] have used the modern taxonomy to describe the several manufacturers' different modes. It is important to understand that many of the modern modes have not been tested in infants and children. Many of the modes are currently being investigated in adults. The following is a description of some of the most common modes used in infants and children, as well as some newer modes in more detail.

Commonly Used Mandatory Modes

The two most common forms of controlled mandatory mechanical ventilation modes that are used in infants and children are pressure-limited time-cycled and volume-controlled time-cycled modes of ventilation. Pressure-limited time-cycled ventilation would be classified as PC-CMV or PC-IMV according to the modern taxonomy. Similarly, volume-controlled time-cycled ventilation would be classified as VC-CMV or VC-IMV. Fig. 57.8 shows pressure-time curves for some of the mandatory modes of ventilation.

Volume-Controlled Mandatory Breaths

Volume-controlled ventilation can be delivered by either volume-cycled breath, where inspiration is terminated after a preset volume is delivered and inspiratory

time is allowed to vary, or volume-controlled time-cycled breaths, where the cycling mechanism is preset time and the tidal volume delivered is regulated by adjusting the inspiratory flow rate. In volume-controlled ventilation, the tidal volume is delivered throughout inspiration. The peak inspiratory pressure (PIP) is variable and depends on the flow rate, total resistance, and total compliance of the ventilator circuit and the patient's lungs. Changes in resistance or compliance will be reflected by an increase in PIP, and the ventilator can be set to alarm at a pressure limit that is generally set 5 to 10 cm above the PIP.

Most modern ventilators deliver the preset tidal volumes reliably, but the tidal volumes delivered to the patient on a breath-to-breath basis may not always be constant. The tidal volume delivered by the ventilator is distributed among the ventilator circuit, airways, and patient's lungs. The compliances and resistances of the ventilator circuit, the endotracheal or tracheostomy tube, and the patient independently and together affect the distribution of tidal volume delivered by the ventilator. A decrease in the compliance or an increase in the resistance of the ventilator circuit will affect the actual tidal volume delivered to the patient. The ventilator circuit includes an internal volume and external tubing. The actual tidal volume or the effective tidal volume (VT_{eff}) delivered to the patient can be approximated by the following formula:

$$VT_{eff} = VT_{del} + VT_{circuit}$$

where VT_{del} is tidal volume delivered by the ventilator and $VT_{circuit}$ is the volume of gas that is distributed to the ventilator circuit.

VT_{del} is equal to the inspired tidal volume, when there is no leak in the total respiratory system. When there is a leak in the system, however, such as with the use of uncuffed endotracheal tubes, then VT_{del} is less than the inspired tidal volume. $VT_{circuit}$ can be estimated by the following formula:

$$VT_{circuit} = C_{vent} \times (PIP - PEEP)$$

where C_{vent} is the compliance of the ventilator circuit, *PIP* is the peak inspiratory pressure reached in the circuit during inspiration, and *PEEP* is the level of positive end-expiratory pressure.

An increase in resistance or compliance of the ventilator circuit (including the endotracheal tube) or the patient's airways or lungs will increase the time constant to inflation. If the inspiratory time is less than five times the time constant of the whole respiratory system, which includes the ventilator circuit and the patient's airways, then the VT_{del} will be less than the preset tidal volume. During inspiration, after the tidal volume is delivered, an inspiratory hold will maintain inspiratory pressure and prolong the duration of inspiration (see Fig. 57.8). During exhalation, expiratory flow curves depend on the type of expiratory resistance or PEEP valve in the system.

Pressure-Limited Mandatory Breaths

Pressure-limited ventilation can be either pressure-cycled or pressure-limited time-

cycled ventilation. In pressure-cycled ventilators, inspiration is terminated when a preset pressure limit is reached. In this mode of ventilation, the inspiratory time may vary depending on the changes in resistance and compliance of the total respiratory system. This mode of ventilation is not widely used these days except for intermittent positive pressure breathing treatments. Pressure-limited, time-cycled ventilation is most commonly used in the neonate with respiratory distress syndrome and in children with acute respiratory distress syndrome (ARDS). In this mode, inspiratory and expiratory times are constant and the PIP reaches a preset limit quickly early in inspiration and is then maintained at that level during the rest of the inspiratory phase. Usually a high flow rate is used (4–10 L/kg/min). The tidal volume delivered depends on the compliance and resistance of the ventilator circuit and the patient's lungs. Pressure-controlled ventilation results in higher mean airway pressure for the same amount of minute ventilation. Fig. 57.11 shows the time course of changes in airway pressure, inspiratory flow, and lung volume with normal lungs, lungs with decreased compliance, and lungs with increased resistance. As shown in Fig. 57.11, with PIP remaining the same, lung volume delivered is affected by changes in lung compliance and airway resistance. Factors that would increase mean airway pressure during pressure-controlled ventilation are shown in Fig. 57.12.

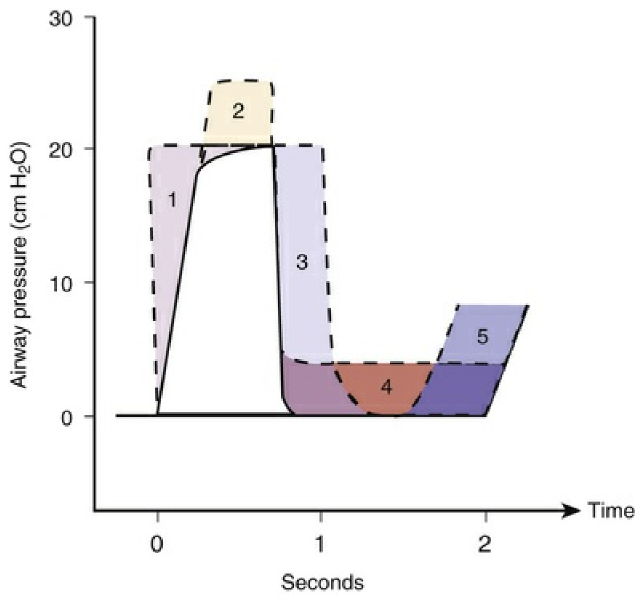

FIG. 57.12 Factors that increase mean airway pressure during pressure-controlled ventilation: *(1)* increased inspiratory flow rate, *(2)* increased preset pressure limit, *(3)* increased inspiratory time, *(4)* increased positive end-expiratory pressure, and *(5)* increased ventilator rate. Note that with each maneuver, the area under the curve increases. Area under the curve represents mean airway pressure. (Reproduced with permission from Goldsmith JP, Karotkin EH, eds. Assisted Ventilation of the Neonate. Philadelphia: WB Saunders; 1988.)

Continuous Flow Versus Demand Flow

Some ventilators that can provide pressure-limited ventilation have both inspiratory and expiratory valves. Once PIP is reached, both inspiratory and expiratory valves

close and the lung is held in inflation until the end of inspiration. For use in infants, ventilators were modified to provide continuous flow throughout the respiratory cycle.[17] A continuous flow device refers to a ventilator in which the flow of respiratory gas occurs throughout the respiratory cycle. Most infant ventilators are continuous flow devices (eg, Infant Star, Baby Bird). In most continuous flow infant ventilators, inspiratory valves are lacking and the cycling is controlled by the exhalation valve. Closure of the exhalation valve begins inspiration, and the flow of gas going through the circuit is diverted to the patient. If the inspiratory flow rate is low (1–3 L/kg) and if the PIP is not limited, the tidal volume delivered by the patient can be calculated from the inspiratory flow rate and inspiratory time. This would result in a time-cycled, volume-controlled breath. For pressure-control ventilation, the flow rates used are usually higher (4–10 L/kg). Once the preset PIP is reached, the excess flow is vented through a pressure relief valve and the lungs are maintained in inflation throughout the rest of inspiration. During exhalation there is continuous flow of gas, allowing the patient to breathe from the circuit rather than open a demand valve. A demand flow ventilator refers to a ventilator that allows inspiratory flow of gas to the patient between ventilator breaths through a demand valve that is opened by the patient's inspiratory efforts. Work of breathing is higher with a demand flow ventilator compared with a continuous flow device because of the effort required to open the demand valve.

CPAP/PEEP

CPAP refers to the maintenance of positive airway pressure throughout the respiratory cycle with no positive pressure breaths being delivered to the patient. PEEP refers to the maintenance of positive airway pressure above atmospheric pressure at the airway opening at end expiration.[21] CPAP/PEEP can be applied by a variety of devices. These include (1) an underwater column, (2) a water-weighted diaphragm, (3) a venturi valve, (4) a spring-loaded valve, (5) a pressurized exhalation valve, (6) a magnetic valve, and (7) a fixed or adjustable orifice. Devices that retard expiratory flows (eg, venturi valve, fixed, or adjustable orifice) tend to produce higher mean airway pressure than those that do not retard expiratory flow rates.

CPAP may be provided by several means:

1. Endotracheal CPAP[5,22]: This is the most reliable method of applying CPAP. The advantages of endotracheal CPAP are precise control of airway pressure and FiO_2; access to the airway for tracheobronchial toilet; maintenance of enteral feeding through a nasogastric tube; and, if necessary, immediate institution of mechanical ventilation. The disadvantages are those associated with those of endotracheal intubation and the long-term presence of an artificial airway.

2. Nasal CPAP: Specially designed nasal prongs,[23] a single cannula or a shortened uncuffed endotracheal tube inserted into the nasopharynx, and nasal masks[24] provide a means of applying CPAP. Because of the location in the nasopharynx, there will be a loss of pressure in the hypopharynx so that the actual CPAP delivered to the trachea may vary. This technique is easy to apply and can be instituted by less-skilled personnel. This technique is most useful in infants who are obligatory nose breathers. Mouth breathing reduces the efficiency of this technique considerably.

Nasal prongs are more prone to obstruction with thick secretions and require proper humidification and frequent suctioning. Nasal prongs have also been reported to increase the work of breathing.[25]

3. Facemask CPAP: A tight-fitting mask is placed on the face covering the nose and mouth. CPAP is provided with the application of positive airway pressure to the mask. This technique is only useful in patients who are alert and cooperative, without a tendency for nausea and vomiting. A tight-fitting mask may produce pressure lesions on the face if applied too tight. Gastric distention with vomiting and aspiration are potential problems.

The primary effect of CPAP/PEEP is an increase in end-expiratory lung volume due to the increased P_{tp}. In lung diseases characterized by increased closing volume and decreased FRC, alveoli are unstable and tend to collapse. Recruitment of collapsed alveoli requires a P_{tp} greater than that required to sustain inflation once the alveoli are open. An increase in FRC above the closing volume restores this balance, prevents alveolar collapse, and maintains alveolar stability (Fig. 57.13). This reduces the magnitude of V/Q mismatching because of improved distribution of alveolar ventilation.[26,27] Airway closure and alveolar collapse can be prevented if the level of CPAP/PEEP is above the critical opening pressure. In lung disease with nonuniform or heterogeneous parenchymal involvement, CPAP/PEEP may hyperinflate normal lung segments, and this hyperinflation results in redistribution of blood toward the diseased segments, increasing intrapulmonary shunt on one hand and increasing alveolar dead space on the other (Fig. 57.14).

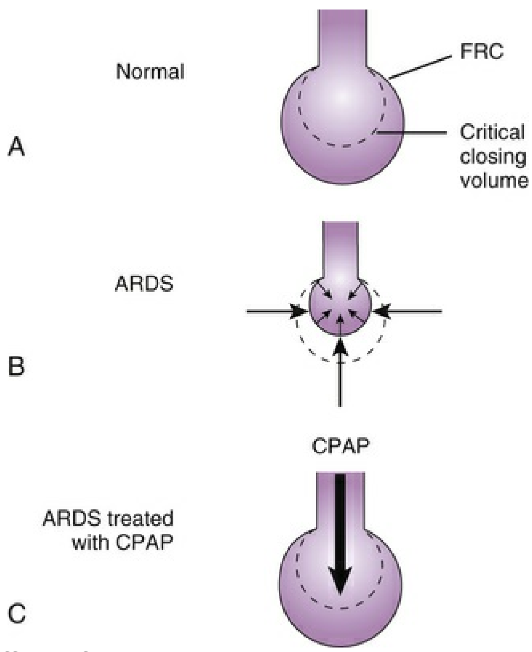

FIG. 57.13 Effect of continuous positive airway pressure (CPAP) on functional residual capacity (FRC). In normal lungs *(A)*, FRC is greater than critical closing volume. In acute respiratory distress syndrome (ARDS) *(B)*, FRC is less than critical closing volume. CPAP restores FRC to be greater than critical closing volume and prevents alveolar collapse *(C)*. (Reproduced with permission from Kirby RR, Smith RA, Desautels DA. Mechanical Ventilation. New

York: Churchill Livingstone; 1985.)

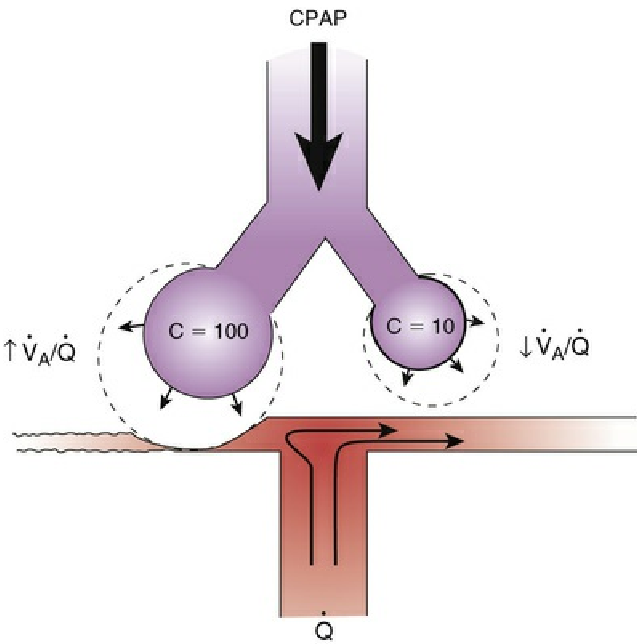

FIG. 57.14 Effect of continuous positive airway pressure (CPAP) on nonhomogenous lung disease. CPAP increases functional residual capacity (FRC) in the lung segment with decreased ventilation-perfusion ratio ($\dot{V}A/\dot{Q}$) and decreases shunt reaction. CPAP overdistends lung segments with high $\dot{V}A/\dot{Q}$ and redistributes blood toward the segments with low $\dot{V}A/\dot{Q}$, increasing the amount of shunt. The net effect depends on the balance between the two. (Reproduced with permission from Kirby RR, Smith RA, Desautels DA. Mechanical Ventilation. New York: Churchill Livingstone; 1985.)

Selection of Parameters for Mandatory Breaths

The first parameter is the tidal volume. A practical approach to determining an adequate tidal volume is to evaluate the desired degree of chest expansion during manual ventilation and reproduce that when the patient is connected to the ventilator. A desirable VT_{eff} for most patients is 8 to 10 mL/kg. Patients with normal lung compliance may require a preset tidal volume of 12 to 15 mL/kg to produce a VT_{eff} of 8 to 10 mL/kg. Ideally, the end-inspiratory alveolar pressure should be less than 30 cms of H_2O. The end-inspiratory alveolar pressure can be measured using an inspiratory hold maneuver. With an inspiratory hold, inspiratory flow is stopped, both inspiratory and expiratory valves are closed, and the proximal airway pressure equilibrates with the alveolar pressure. The end-inspiratory hold pressure is called the "pause pressure," "plateau pressure," or simply "end-inspiratory airway pressure." A large VT_{eff}, especially that which results in an end-inspiratory airway pressure greater than 40 cm of H_2O, should be avoided. During mechanical ventilation, end-inspiratory alveolar pressure can be estimated through the measurement of the end-inspiratory airway pressure with an end-inspiratory hold

maneuver.

Ventilator rate is the next parameter to be selected. The initial rate selected depends on the age of the patient and ventilatory requirements of the patient and may subsequently be adjusted according to the $PaCO_2$. The initial ventilator rate for a newborn infant usually ranges from 25 to 30 breaths per minute; for a 1-year-old, between 20 and 25 breaths per minute; and for an adolescent, from 15 to 20 breaths per minute. The inspiratory time is selected to provide an inspiratory-to-expiratory time (I : E) ratio of at least 1 : 2 in most patients. Inspiratory time can be set as either a percentage of the total respiratory cycle or as a fixed time in seconds depending on the ventilator. Inspiratory time must be selected to allow sufficient time for all lung segments to be inflated. In heterogenous lung disease with varying regional time constants, a short inspiratory time may not be sufficient to inflate all lung segments and may contribute to underventilation and underinflation. Similarly, sufficient expiratory time must be provided for all lung segments to empty. If inspiration starts before the lung has completely emptied, this will result in air trapping and inadvertent positive end-expiratory pressure. The I : E ratio can be adjusted according to the pathophysiologic cause of the lung disease. In infants with bronchiolitis and in children with asthma, the expiratory time may have to be lengthened to avoid air trapping.

PEEP is the next parameter to be selected. The level of PEEP will depend on the clinical circumstance. PEEP increases mean Paw during both volume-controlled and pressure-controlled ventilation, which results in a higher mean lung volume. The goals of PEEP are (1) increasing end-expiratory lung volume above closing volume to prevent alveolar collapse, (2) maintaining stability of alveolar segments, (3) improving oxygenation, and (4) reducing work of breathing. The optimum PEEP is the level at which there is an acceptable balance between the desired goals and undesired adverse effects. The desired goals are (1) reduction in inspired oxygen concentration to "nontoxic" levels (usually ≤50%); (2) maintenance of PaO_2 or SaO_2 (arterial oxygen saturation) of more than 60 mm Hg or more than 90%, respectively; (3) improvement of lung compliance; and (4) maximal oxygen delivery.[28-30] Arbitrary limits cannot be placed on the level of PEEP or mean airway pressure that will be required to maintain adequate gas exchange. When the level of PEEP is high, peak inspiratory pressure may be limited to prevent it from reaching dangerous levels that contribute to air leaks and barotrauma.

FiO_2 is the next parameter to be selected. FiO_2 is adjusted to maintain an adequate PaO_2. High concentration of oxygen can produce lung injury and should be avoided. The exact threshold of inspired oxygen that increases the risk of lung injury is not clear. An FiO_2 less than 0.5 is generally considered safe. In patients with parenchymal lung disease with significant intrapulmonary shunting, the major determinant of oxygenation is lung volume, which is a function of the mean airway pressure. With a shunt fraction of more than 20%, oxygenation may not be substantially improved by higher concentrations of oxygen.

Other Modes Used in Infants and Children

Pressure-Support or Pressure-Support Ventilation

A pressure-supported breath is one that is patient triggered, pressure controlled, and

flow cycled. It is an assisted spontaneous breath in which the ventilator assists the patient's own spontaneous effort with a mechanical breath with a preset pressure limit. Fig. 57.15 shows the important components of a pressure-support breath. As with any form of support that is designed to respond to the patient's effort, the inspiratory pressure assist of PSV requires a signal to trigger the demand valve to initiate flow.[42] Since this breath is patient triggered and patient cycled with pressure as the control variable, it would be classified as PC-CSV according to modern taxonomy.

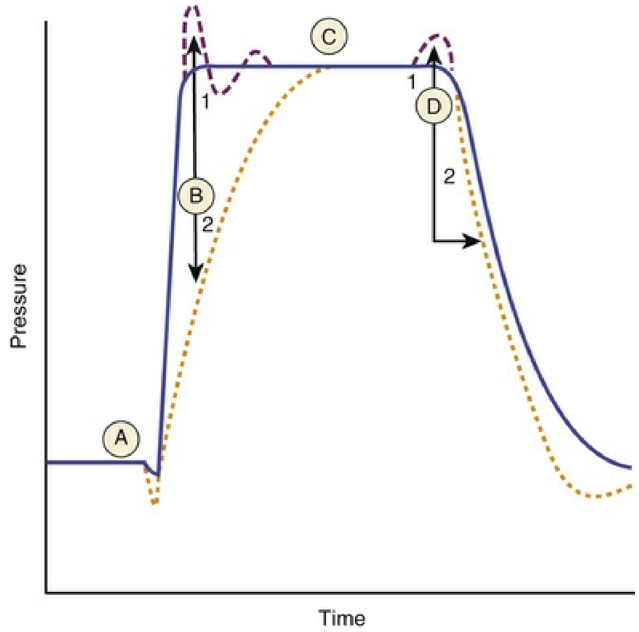

FIG. 57.15 Components of a pressure-support breath. *Point A* is the patient's effort indicated by a negative deflection. When the ventilator senses this trigger (change in pressure or flow), it will deliver flow to reach the desired pressure-support level *(Point B)* as rapidly as possible. Ventilator-delivered flow is then servo-adjusted to patient demand to maintain this pressure plateau *(Point C)*. Inspiration is terminated when a minimal flow criterion is reached *(Point D)* and airway pressure returns to baseline. (Reproduced from MacIntyre NR. Pressure support ventilation. Mechanical ventilation and assisted respiration. In Grenvik A, Downs J, Rasanen J, Smith R, eds. Contemporary Management in Critical Care. New York: Churchill Livingstone; 1991.)

The patient's spontaneous breath creates a negative pressure (pressure triggering) or a change in flow through the circuit (flow triggering), which triggers the ventilator to deliver a breath. With initiation, the machine delivers high inspiratory flow to achieve a peak airway pressure level that is selected by the operator.[32-34] The pressure limit stays constant as long as the patient's inspiratory effort is maintained with a variable gas flow rate from the ventilator.[33,34] As inspiration continues, the inspiratory flow rate decreases. A threshold reduction in the flow rate is a signal for the termination of the inspiratory assist, with the opening of an expiratory valve, after which passive exhalation occurs.[32-34] The termination signal can be a predetermined percentage of the peak inspiratory flow (10% or 25%) or a fixed flow (usually 5 L/min).[35-37] Many ventilators also incorporate backup flow termination criteria, such as the duration of inspiration greater than 5 seconds or an increase in

the airway pressure above the set pressure-support level (eg, when a patient attempts to cough). In summary, PSV is patient triggered, pressure limited, and flow cycled. PSV is entirely dependent on the patient's effort; if the patient becomes apneic, the ventilator will not provide any mechanical breath.

Martin et al. demonstrated in a bench study of a modified pediatric volume ventilator that work of breathing during pressure-support ventilation can be reduced by a high sensitivity and a low-volume displacement in the circuit.[38] The effectiveness of pressure-support ventilation in children was first demonstrated in six children (age 3–5 years) after cardiac surgery.[39] With increasing pressure-support levels, the tidal volume increased with a corresponding decrease in respiratory frequency.[39] Increasing pressure support also improved thoracoabdominal synchrony in infants.[40]

Dual Control Modes

Dual Control Within a Breath

These modes allow the ventilator to deliver a pressure-controlled breath or switch from a pressure-controlled breath to a volume-controlled breath within the breath. This is shown in Fig. 57.15. This mode is referred to as VAPS (Bird 8400ST and Tbird, Bird Corp., Palm Springs, California, USA) and pressure augmentation (PA) (Bear 1000). Both techniques can operate during mandatory breaths (pressure-limited time-cycled) or pressure-supported breaths. During VAPS and PA, the clinician must set the respiratory frequency, peak flow, PEEP, inspired oxygen concentration, trigger sensitivity, and minimum desired tidal volume. During VAPS or PA, the ventilator's inspiratory flow waveform is constant (square). Additionally, the pressure-support setting must be set. During pressure support, VAPS and PA can be considered a safety net that always supplies a minimum tidal volume. A VAPS or PA breath may be initiated by the patient or time triggered. Once the breath is triggered, the ventilator attempts to reach the pressure-support setting as quickly as possible. This portion of the breath is the pressure-control portion and is associated with a rapid variable flow, which may reduce the work of breathing. As this pressure level is reached, the ventilator's microprocessor determines the volume that has been delivered from the machine (NOTE: This is not exhaled tidal volume), compares this measurement with the desired tidal volume, and determines whether the minimum desired tidal volume will be reached. If the ventilator determines that the ultimate delivered tidal volume will be equivalent to the set tidal volume, the breath is delivered as a pressure-support breath. If the ventilator determines that the ultimate delivered tidal volume will be less than the set tidal volume, then the breath changes from a pressure-limited to a volume-limited breath. At that point inspiratory flow remains constant, and the ventilator increases the inspiratory time until the desired volume has been delivered. Inspiratory pressure will increase above the set pressure-support setting. Setting the high-pressure alarm remains important during VAPS. If pressure increases abruptly, the high-pressure alarm setting is reached and the breath is pressure cycled (Fig. 57.16). VAPS breath can allow the patient a tidal volume larger than the set volume.

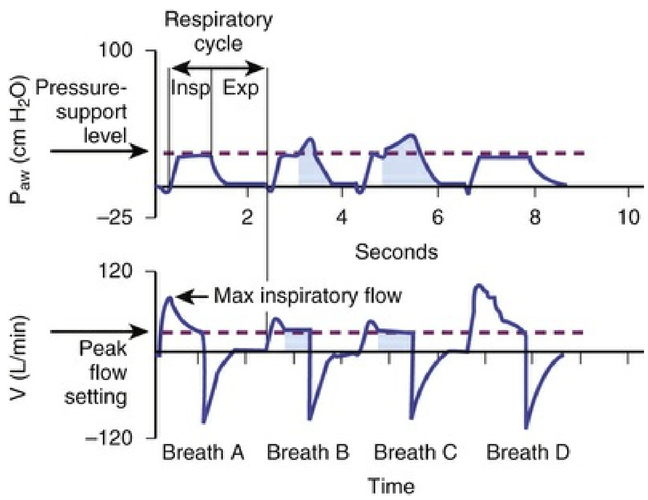

FIG. 57.16 Pressure and flow waveforms illustrating volume-assured pressure support. (Reproduced with permission from Branson RD, MacIntyre NR. Dual-control modes of mechanical ventilation. Respir Care. 1996;41:294-305.)

Mandatory Dual-Control Breath-to-Breath Modes

Dual-control breath-to-breath mode with mandatory pressure-limited time-cycled breaths is referred to as pressure-regulated volume control (PRVC) (with Siemens 300), adaptive pressure ventilation (APV) (with Hamilton Galileo), autoflow (Evita 4), or variable pressure control (Venturi), depending on the manufacturer. In this form of pressure-limited, time-cycled ventilation, delivered tidal volume is used as a feedback control for continuously adjusting the pressure limit. All breaths in these modes are time or patient triggered, pressure limited, and time cycled. One difference between devices is that the Siemens 300 only allows PRVC in the CMV mode. The newer Servo-i ventilator and the other ventilators allow dual-control breath to breath with CMV or SIMV. During SIMV, the mandatory breaths are the dual-control breaths. PRVC is selected on the mode selector switch, and the desired tidal volume is set. A "test breath" is delivered, and total system compliance is calculated. The next three breaths are delivered at a pressure limit that is 75% of that necessary to achieve the desired tidal volume on the basis of the compliance calculation. The ensuing breaths increase or decrease the pressure limit at less than 3 cm H_2O per breath in an attempt to deliver the desired tidal volume. The pressure limit fluctuates between 0 cm H_2O above the PEEP level and 5 cm H_2O below the upper-pressure alarm setting. The ventilator sounds an alarm if the tidal volume and maximum pressure limit settings are incompatible. With changes in lung compliance and resistance, the delivered tidal volume may not be equivalent to the set tidal volume. If the delivered tidal volume is less than the set tidal volume, the pressure limit is increased to achieve the set tidal volume until the pressure limit is equal to a level 5 cm H_2O below the upper pressure limit alarm. The upper pressure-limit alarm must be adjusted with this in mind. It should be set to the maximum allowable pressure plus 5 cm of H_2O. When the delivered tidal volume is larger than the set tidal volume, then the ventilator will lower the pressure limit to achieve the set tidal volume. There is no lower limit for the reduction in the pressure-limit level. This mode of ventilation appears to be most beneficial when there are rapid changes in lung compliance (such as after surfactant administration[41-43]). Clinically controlled

trials are required to evaluate the benefits of PRVC ventilation in acute lung disease, in ventilation of healthy lungs (ie, in patients undergoing neurosurgical procedures), and during weaning from the ventilator.

Assisted Dual-Control Breath-to-Breath Mode

Dual-control breath to breath in the pressure-support mode is simply closed-loop pressure-support ventilation, with tidal volume as the input variable. It is referred to as *volume support* (Siemens 300, Servo-i) and *variable pressure support* (Venturi). All breaths are patient triggered, pressure limited, and flow cycled. Volume support is selected with the mode selector switch, and the desired tidal volume is set. The ventilator initiates volume support by delivering a “test breath” with a peak pressure of 5 cm H_2O when a patient effort is sensed. The delivered tidal volume is measured, and total system compliance is calculated. The subsequent three breaths are delivered at a peak inspiratory pressure of 75% of the pressure calculated to deliver the minimum tidal volume. Each subsequent breath uses the previous calculation of system compliance to manipulate peak pressure to achieve the desired tidal volume. From breath to breath, the maximum pressure change is less than 3 cm H_2O and can range from 0 cm H_2O above PEEP to 5 cm H_2O below the high-pressure alarm setting. The primary cycling mechanism is flow cycling of the pressure-supported breath. Similar to the PRVC mode previously described, the pressure-support level is adjusted to maintain the set tidal volume with changes in compliance and resistance. In addition to the volume-support settings, a mandatory ventilator frequency must be set. This frequency is set according to the age of the patient; the frequency for ages younger than 6 months is 16 to 20 breaths per minute; for 6 months to 2 years, 14 to 18 breaths per minutes; for 2 to 5 years, 12 to 16 breaths per minute; and for older than 5 years, 10 to 16 breaths per minute. A secondary cycling mechanism is activated if inspiratory time exceeds 80% of the set total cycle time. There is also a relationship between the set ventilator frequency and tidal volume. The minute ventilation calculated by the set tidal volume and the backup ventilator rate gives the minimum minute ventilation that needs to be achieved. If the patient is breathing at a frequency faster than the set ventilator rate, then the only adjustment that is made by the ventilator is to manipulate the pressure-support level to achieve the desired tidal volume. The total minute ventilation in this instance will be larger than the minimum level that needs to be achieved. When the patient's breathing rate is less than the set frequency, then the total minute ventilation will decrease to a level below the set minimum level. Next, the tidal volume target is automatically increased by raising the pressure-support level up to a maximum of 150% of the initial set value. If the tidal volume has to be increased beyond the 150% of the initial set value or the minute ventilation cannot be maintained at the set minimum level, then the ventilator will alarm and switch to the PRVC mode to ensure that at least the set minimum minute ventilation is delivered.

AutoMode

AutoMode combines mandatory and assisted dual-control breath-to-breath modes. The patient's effort or lack of breathing effort determines whether the breaths are flow cycled or time cycled. AutoMode is available on the Siemens 300A ventilator. Simplistically, AutoMode can be thought of as the combination of volume support

and PRVC in a single mode. When the patient is breathing spontaneously, then the patient is in volume-support mode. If the patient becomes apneic or is paralyzed, the ventilator provides PRVC. The apneic threshold setting is 12 seconds for adults, 8 seconds for children, and 5 seconds for neonates. The change from PRVC to volume support or from volume support to PRVC is accomplished at equivalent peak pressures.

Automatic Tube Compensation

Automatic tube compensation (ATC) is a technique of overcoming the imposed work of breathing caused by artificial airways available in the Evita 4 ventilator. It accomplishes this by using the known resistive characteristics of the artificial airways. ATC is essentially pressure support in which the ventilator adjusts the pressure support to compensate for the imposed work of breathing by the artificial airways and the flow demand of the patient. The equation for calculating tracheal pressure (Ptrach) is:

$$\text{Ptrach} = \text{Paw} - (\text{K} \cdot \text{V2})$$

where *Paw* is airway pressure, *V* is flow, and *K* is the tube coefficient describing the nonlinear pressure/flow curve of the ETT.

To select the level of ATC required, the operator needs to input type of tube, endotracheal or tracheostomy, and the percentage of compensation desired (10%-100%). Most of the interest in ATC revolves around eliminating the imposed work of breathing during inspiration. Under static in vitro conditions, pressure support can eliminate the endotracheal resistance, but in vivo, where the inspiratory flow demands of the patient are changing, a single level of pressure support is unlikely to be effective. Moreover, there are no in vivo measurements of the minimal pressure support needed to overcome the endotracheal tube resistance. During periods of tachypnea, the level of pressure support no longer eliminates work imposed by the endotracheal tube. Additionally, the resistance of the endotracheal tube creates a condition early in the breath in which ventilator flow is high, tracheal pressure remains low, and undercompensation for imposed work occurs.[44] Late in the breath, when pressure begins to equilibrate during the pressure plateau, pressure support tends to overcompensate, prolong inspiration, and exacerbate overinflation.[44] During expiration, however, there is also a flow-dependent pressure decrease across the tube. ATC also compensates for this flow-resistive component and may reduce expiratory resistance and unintentional hyperinflation. During expiration, the calculated tracheal pressure is greater than airway pressure.

Airway Pressure Release Ventilation

Airway pressure release ventilation (APRV) is a method of mechanical ventilation introduced by Stock and Downs.[45,46] It was based on the premise that most patients with ARDS required positive pressure support to maintain an adequate lung volume and required minimal, if any, ventilatory assistance.[45,46] These authors theorized that if a sufficiently high level of CPAP was provided with a high gas flow rate, it would maintain an adequate lung volume and oxygenation while ventilatory needs would be met entirely by spontaneous breathing. If additional ventilatory assistance were

to be required, CPAP level could be abruptly reduced for a short period of time and this could be repeated several times in a minute to enhance ventilation. It is important to review the original design of an APRV circuit and contrast that with what is currently available in ventilators.

The original circuit included a CPAP device and a mechanism to release airway pressure periodically to some desired low pressure (Fig. 57.17). Gas was delivered from a high-pressure tank through a Venturi device at a flow rate of 90 to 100 L/min. The gas flowed through a T-piece circuit, which has a threshold-resistor expiratory valve to generate CPAP. Proximal to the threshold resistor, an automatic switch was placed to periodically allow gas to bypass the expiratory valve. This bypass could be set to either ambient pressure or another resistor valve, which would generate a pressure much lower than the CPAP pressure (Fig. 57.17). A timing device controlled the opening and closing of the switch. In the original description, the gas flow through the circuit was continuous and allowed unrestricted spontaneous breathing. In the original report, APRV was used in 10 dogs with normal lungs and abnormal lungs. With normal and injured lungs, APRV could maintain the same level of oxygenation for the same mean airway pressure but with a lower peak inspiratory pressure. The I : E ratio used was about 1 : 0.7 with a rate of about 20/min. With lung injury, APRV could maintain the same oxygenation with a lower dead space.[45] Hemodynamic status was similar during both modes. Several studies with acute respiratory failure have shown that APRV results in improvement in gas exchange with much lower airway pressures.[45,47-49] Lower peak airway pressures are the consistent major advantage of ARPV. Because airway pressures are lower, APRV results in less adverse cardiovascular effects than IMV.[47,49]

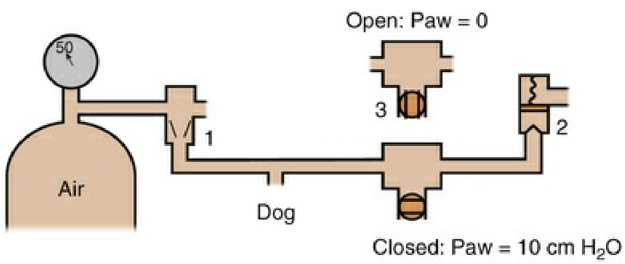

FIG. 57.17 Airway pressure release ventilation. Gas is delivered from a high-pressure source through the inspiratory limb of a T-piece circuit *(1)*. When the switch in the expiratory limb *(3)* is closed, continuous positive airway pressure is generated by the expiratory resistor valve *(2)*. When the switch is open, gas escapes through the bypass limb to a predetermined pressure.

In the accompanying editorial, the authors described how APRV would be used:[46]

"To provide APRV, continuous positive airway pressure (CPAP) is maintained so that the patient can breathe spontaneously without significant airway pressure (Paw) fluctuation. The appropriate level of CPAP may be determined by observing, measuring, and calculating a variety of physiologic responses to varying levels of CPAP. Changes in respiratory effort, respiratory rate, depth of respiration, PaO_2, calculated right-to-left shunting of blood, and lung-thorax compliance help the

clinician to determine an appropriate Paw. Once a satisfactory level of CPAP is selected, if mechanically assisted ventilation is required, APRV may be initiated by cyclically releasing Paw to a lower level. This decreased Paw will allow gas to passively leave the lungs, eliminating CO_2. When the brief release period ends, Paw rapidly returns to the original CPAP level, thus increasing lung volume. The degree of ventilatory assistance provided by the APRV will be determined by the frequency of pressure release, the duration of pressure release, the CPAP level, the pressure release level, the patient's lung-thorax compliance, and flow resistance in the patient's airways and in the pressure release valve."

The authors also stated that:

"A continuous or intermittent flow of pressured gas and a variety of threshold resistor valves may be independently, or in combination, used to provide CPAP and to allow pressure release. Gas flow must at least equal the patient's peak inspiratory flow."[46]

With APRV, minute ventilation occurs with both spontaneous breaths and the periodic inflation and deflation that occur with the two levels of airway pressure. Gas exchange can occur throughout the respiratory cycle.

APRV is, by the modern taxonomy, PC-IMV usually using an inverse I : E ratio. Spontaneous breaths are also allowed during the mandatory breaths. The mandatory breaths applied by APRV are time-triggered, pressure-targeted, time-cycled breaths, which can be synchronized to a patient's breathing. Four major variables determine an APRV breath: Phigh, Plow, Thigh, and Tlow. Phigh is defined as the pressure of the triggered mandatory breath and Thigh is the duration that Phigh is maintained. Plow is the release pressure and Tlow is the time of the pressure release. Currently, some of the modern ventilators have incorporated features that allow spontaneous breathing through a demand-flow system during both the inspiratory and expiratory phases of a pressure-controlled time-cycled breath. These are called by different names such as *biphasic positive airway pressure* and *intermittent mandatory pressure-release ventilation.* These different modes have been classified under the acronym APRV. Some ventilators incorporate pressure support to be provided for the spontaneous breaths during these modes. It is clear that the patient-ventilator interactions are clearly different between the original APRV circuit and the modern "APRV" systems. Generally, demand-flow systems increase the trigger work of breathing and therefore are not necessarily unrestricted, especially in infants and children.

APRV use in children is relatively new and not well studied. Most of the articles published on the use of APRV are mostly case reports or case series.[50-64] It has been used mainly as a rescue therapy with refractory hypoxemia. Most of the studies showed improvement in oxygenation, but improvement was probably related to using a higher mean airway pressure with APRV.[50-64] None of the studies used the original approach as suggested by the original authors.[50-64] Habashi published a review of APRV with guidelines for optimal settings for adults and pediatric patients.[65] These guidelines have not been formally validated in any prospective study.

Proportional Assist Ventilation

Proportional assist ventilation (PAV) is a mode of mechanical ventilation based on the equation of motion. It accomplishes this by taking into account the instantaneous elasticity and flow resistance of the respiratory system. When PAV is initiated, the ventilator provides "test breaths" (controlled breaths with fixed flow and volume), which allows estimation of the respiratory system mechanics, minute ventilation, and the work of breathing (resistive and elastic ventilator muscle loads). These are repeated at regular intervals to recompute the load estimations. These estimations provide inputs for the PAV algorithm. The clinician can set the level of PAV (usually a percentage of the total work) to be provided breath-by-breath by the ventilator. The design of PAV allows the ventilator to change the pressure output (pressure control) to always perform work proportionally to patient effort.[66,67] In PAV, when the patient makes an inspiratory effort, the ventilator monitors the instantaneous rate and volume of gas flow.[66,67] The ventilator then amplifies the patient's effort during the breath by applying an additional pressure, which is based on the equation of motion. PAV can also be conceptualized as simply PSV, in which the level of pressure support is adjusted as a multiple of the sum of the volume and flow signals. The ventilator tries to maintain a constant percentage of work performed by the patient per breath irrespective of the volume of the breath or the inspiratory flow of the breath.

Unlike conventional breaths, where volume, flow, or pressure is predetermined, in PAV the ventilator applies the pressure in relation to the patient effort after the breath has started.[66,67] The tidal volume and minute ventilation are completely determined by the patient. In PAV, the ventilator unloads the patient's effort to a preset proportion of the patient's effort and the ventilating pressure is shared between the patient and ventilator. PAV is designed to improve patient-ventilator synchrony. Exhalation is generally flow cycled. Unlike conventional modes, in PAV, the pressure applied by the ventilator is directly proportional to the patient effort (ie, pressure applied by the ventilator increases as the patient effort increases to unload the respiratory muscles and decreases as the patient effort decreases).[66-68] There are few clinical studies in infants and children.[69-72] These studies show that PAV can maintain gas exchange with lower airway and transpulmonary pressure and improve thoracoabdominal synchrony.[69-72] Despite these studies, PAV is currently not recommended for patients less than 20 kg.

Neurally Adjusted Ventilatory Assist

In neurally adjusted ventilatory assist (NAVA), the ventilator assist is controlled by changes in electromyographic activity of the diaphragm.[73] NAVA is a mode of ventilation in which the ventilator assists a spontaneous breath with a pressure that is proportional to the integral of the electrical activity of the diaphragm (EAdi).[73] NAVA involves the transesophageal recording of EAdi using a specifically designed catheter. In order for NAVA to be effective, it is critical that the esophageal catheter measuring EAdi be positioned correctly.[74] The EAdi signal should reliably monitor and control the ventilatory assist.[75] The EAdi signal is used to both trigger and cycle-off the breath. With NAVA, the magnitude of the ventilator support will depend on a mathematic function that represents diaphragmatic electrical activity times a gain factor as shown by the equation:

$$\mathrm{Paw} = \mathrm{NAVA\ level} \times \mathrm{EAdi}$$

where *Paw* is the instantaneous airway pressure (cms H_2O), *EAdi* is the instantaneous integral of the diaphragmatic electrical activity signal (μV), and the *NAVA* level (cms H_2O/μV or per arbitrary unit) is a proportionality constant or gain factor. Similar to PAV, this allows the patient to control the tidal volume and flow within the breath. By coordinating the diaphragmatic activity and the ventilator support, the delivered pressure should be synchronous with EAdi and the level of assistance can be automatically adjusted depending on the changes in neural drive, respiratory mechanics, and inspiratory muscle function.[73] It is critical to understand that using EAdi to estimate respiratory center output requires that the phrenic nerve is intact and functioning and assumes that the diaphragm is the primary inspiratory muscle.

It is important to understand that pressure, flow, volume, or time during inspiration is not predetermined. In NAVA, the ventilator assists the spontaneous breath with a pressure applied per millivolt of diaphragmatic electrical activity and the ventilating pressure is shared between the patient and ventilator. NAVA is designed to improve patient-ventilator synchrony. Similar to PAV, when the patient effort increases, the pressure applied by the ventilator during the breath also increases to unload the patient effort in NAVA. Studies in infants and children demonstrate that NAVA is feasible and may be of potential advantage over other modes of mechanical ventilation.[74-80] By allowing better patient-ventilator synchrony, it may be possible to reduce the amount of sedation that needs to be used in these children.

Mandatory Minute Volume Ventilation

Mandatory minute volume ventilation (MMV) was first introduced by Hewlett et al.[81] in 1977. In this mode, the patient is guaranteed a preset delivered minute ventilation. If the spontaneous minute ventilation exceeds the preset value, then the ventilator reduces the rate to zero and does not deliver a mechanical breath. If there is no spontaneous minute ventilation, then the ventilator will deliver sufficient breaths to match the preset minute ventilation. If the spontaneous minute ventilation is insufficient to match the preset value, then the ventilator will provide the remainder of the minute ventilation. Different mechanisms are used by manufacturers to achieve this goal. In the Ohmeda CPU1 ventilator, the preset minute ventilation is compared with the patient's total minute ventilation (spontaneous and mechanical) every 24 cycles and then adjusted. In the Engstrom Erica ventilator, it is done on a breath-by-breath basis. Currently there is not much experience with MMV in pediatric patients. The indications of MMV are in patients after abdominal surgery, especially with complications; patients who are recovering from respiratory muscle paralysis (eg, Guillain-Barré syndrome, myositis, myasthenia gravis); and patients who have widely fluctuating respiratory drive (encephalopathy).

Ventilation for Selected Underlying Pathophysiology

Primary Respiratory Muscle Failure (“Respiratory Pump Failure”)

The primary difficulty in these disorders is inadequate ventilation due to weakness of the respiratory muscles (pump failure). Tidal volumes and ventilatory rates are set to provide normal minute ventilation to maintain normocarbia. Complete control of ventilation may result in disuse muscle atrophy and complicate weaning from mechanical ventilation. Therefore spontaneous breathing should be encouraged as much as possible. Assisted ventilation is a useful mode of ventilation in these disorders because the trigger sensitivity can be adjusted to encourage spontaneous breathing on the one hand and prevent muscle fatigue on the other. FiO_2 is usually kept to a minimum (≤0.3) because these disorders are not associated with inadequate oxygenation. In chronic hypoventilation, hypercarbia is often acceptable, provided the arterial pH is within the normal range. PEEP is usually set at a relatively low level (3–5 cm H_2O).

Disorders With Airway Obstruction

Provision of an artificial airway relieves respiratory distress due to upper airway obstruction (eg, epiglottitis, croup). Respiratory failure due to lower airway obstruction poses a special problem during mechanical ventilation. Depression of cardiac output and hypotension may occur during intubation because of the institution of positive airway pressure to already hyperinflated lungs. This causes further impedance to venous return and increased pulmonary vascular resistance. Volume-controlled ventilation is the preferred mode of ventilation. Inspiratory-expiratory ratio should be at least 1 : 2. The expiratory time required depends on the severity of the lower airway obstruction. If the expiratory time is inadequate to empty the lung, “auto-PEEP” or “inadvertent PEEP” will result. Inadvertent PEEP results in air trapping and hyperinflation with its attendant complications. The level of PEEP selected for patients with lower airway obstruction is controversial. There are two schools of thought: “low PEEP” and “high PEEP.” Low PEEP advocates usually apply a PEEP of 3 to 5 cm H_2O because of the concern for pulmonary barotrauma from air trapping and alveolar hyperinflation. In lower airway disease, air trapping often results in an end-expiratory alveolar pressure that is higher than the proximal airway pressure because of incomplete emptying of the alveoli. This results in “auto-PEEP” or “inadvertent PEEP.” End-expiratory lung volume and therefore the level of alveolar inflation will not be affected by the level of proximal set PEEP as long as it is less than the amount of auto-PEEP. In adults with severe asthma, high levels of PEEP, which is closer to the level of auto-PEEP, have been shown to decrease the magnitude of air trapping and work of breathing without significant complications.[82-85] In children with tracheomalacia or bronchomalacia, PEEP decreases the airway resistance by distending the airways and preventing dynamic compression during expiration. The use of low levels of PEEP compared

with high levels has been described previously.

Parenchymal Lung Disease

ARDS, hyaline membrane disease of the newborn, and interstitial pneumonias are examples of parenchymal lung disorders that are characterized by a reduction in FRC, an increase in closing volume above FRC, and diffuse subsegmental atelectasis. These diseases are characterized primarily by inadequate oxygenation due to V/Q mismatching and intrapulmonary shunting. Therapy should be directed toward maintaining lung volumes above closing volume throughout the respiratory cycle, increasing FRC above closing volume, and reducing V/Q mismatching and intrapulmonary shunting. The most effective method of achieving these goals is with an increase of mean lung volume, which is usually obtained with an increase of the mean airway pressure. During spontaneous breathing without any ventilatory assistance, CPAP is the most reliable method to increase lung volume. CPAP is effective in improving oxygenation in hyaline membrane disease and ARDS.[85,86] During positive pressure breathing, the level of PEEP required to maintain adequate oxygenation primarily depends on the severity of the underlying lung disease. The degree of intrapulmonary shunting, ventilation-perfusion mismatching, alveolar edema, alveolar collapse, and decreased compliance is directly proportional to the severity of lung disease. As the severity of lung disease increases, the airway pressures required to maintain adequate gas exchange also increase. Therefore arbitrary limits cannot be placed on the level of PEEP or mean airway pressure that will be necessary to maintain adequate gas exchange. Tidal volumes should be limited to 6 to 8 mL/kg. Studies in adults, including the ARDS Network study, have demonstrated that using high tidal volumes of 12 mL/kg is detrimental to patient outcome.[87,88] When high levels of PEEP are used, PIP may reach levels that contribute to pulmonary air leak and barotrauma. Attempts to decrease PIP with the reduction of tidal volume will result in decreased mean airway pressure, mean lung volume, and decreased minute ventilation. With a high airway pressure maintained throughout inspiration, pressure-control ventilation may provide higher mean airway pressure and maintain a higher mean lung volume compared with volume-control ventilation. A general rule of thumb is to consider switching to pressure-limited time-cycled ventilation when PEEP requirement is more than 10 cm H_2O. For hyperinflation to be avoided, the end-inspiratory pause pressure should not exceed 35 cm H_2O. Hypercapnia may be permitted under these circumstances provided arterial pH is adequate (permissive hypercapnia). It has been recommended that the optimal PEEP should be set above the critical closing or critical opening pressure of the airways. This can be deduced by the lower inflection point generated with static pressure-volume loops (Fig. 57.18). As the lung is inflated from zero end-expiratory pressure, in many lungs there is an abrupt change in compliance as denoted by the "lower inflection point." It is generally thought that this is the critical opening pressure of the airways above which the alveoli and airways remain open. As the lung is further inflated in increments, the pressure-volume slope increases and then abruptly changes direction as noted in Fig. 57.18 as the "upper inflection point." It is generally thought that the upper inflection point reflects overdistention of the alveoli. The general recommendation is to keep the PEEP level above the lower inflection point and the end-inspiratory pause pressure below the upper inflection

point. Currently, bedside use of static pressure-volume loops to set PEEP is not a standard practice in infants and children. Therefore the level of PEEP should be set by titrating the level of PEEP and selecting the level by the maximal level of improvement in oxygenation compliance seen without affecting systemic hemodynamics. The repeated collapse and reopening of the lung units at low lung volume have been shown to contribute to ventilation-induced lung injury.[89-92] A strategy combining recruitment maneuvers, low-tidal volume, and higher PEEP has been shown to decrease the incidence of barotrauma or volutrauma.[89-93]

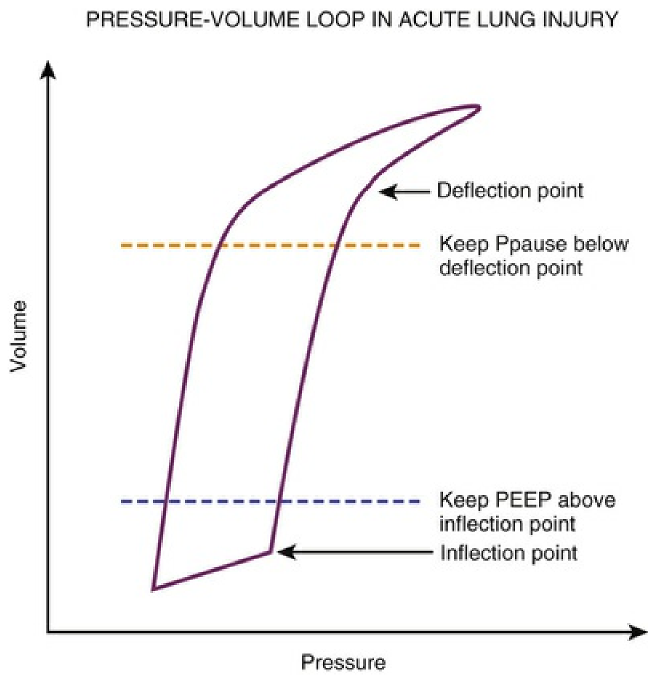

FIG. 57.18 Optimal positive end-expiratory pressure (PEEP) and peak alveolar pressure setting in acute lung injury/acute respiratory distress syndrome on the basis of static pressure-volume loop. The goal is to keep the PEEP level above the lower inflection point and to keep the end-inspiratory pause pressure below the upper inflection point.

Alveolar Recruitment and Derecruitment

Alveolar recruitment, by definition, means opening up of closed alveoli. In ARDS and other parenchymal lung diseases, atelectasis and consolidation are common pathologic features that result in intrapulmonary shunting. The goals of positive pressure support in ARDS are to recruit closed alveoli and present derecruitment of open alveoli. The benefits of optimal lung recruitment and prevention of derecruitment are (1) a reduction in the intrapulmonary shunt fraction and venous admixture resulting in an improvement in arterial oxygenation; (2) improvement in lung compliance; and (3) prevention of repeated alveolar collapse and reopening, which may ameliorate or prevent ventilator-induced lung injury. The primary determinants of alveolar recruitment and derecruitment are transpulmonary pressure and PEEP, both of which increase mean airway pressure. Mean lung volume depends on mean alveolar pressure. Mean airway pressure has been shown

to be an excellent marker of mean alveolar pressure.[94] Increasing mean airway pressure will improve oxygenation if there is alveolar recruitment.

Currently several techniques of alveolar recruitment have been described in the literature. These include manual inflation to high airway pressures, the increase of PEEP in a stepwise manner, application of a sign maneuver, the use of pressure-limited time-cycled ventilation with a high peak inspiratory pressure, and the combination of titrated levels of PEEP with increased inflation pressures. Ventilatory sighs are effective in recruiting alveoli in ARDS.[95] They are effective, however, only from an optimal level of PEEP that does not result in derecruitment. At optimal PEEP, a sigh maneuver increases end-expiratory lung volume and improves oxygenation.[96] Gattinoni et al.[97,98] showed and quantified alveolar recruitment induced by PEEP and showed that the primary role of tidal volume inflation was to open the lung and the primary role of PEEP was to avoid derecruitment. Not all patients have recruitable lungs. In some patients, the lungs may be maximally recruited and any further increase in airway pressures may either cause no change in lung mechanics or gas exchange or result in a deterioration of lung mechanics and gas exchange due to overdistention.[99] The low tidal volume and moderate PEEP approach used in the ARDS Network study has been shown to result in derecruitment in many patients. Richard et al. showed that increasing PEEP or performing periodic recruitment techniques counteracted the derecruitment in these patients.[100] Periodic high levels of PEEP, high inflation plateau pressures, or both have shown to be beneficial in improving lung mechanics and oxygenation, through alveolar recruitment.[101-103]

Prone Positioning

Prone positioning has been proposed as a means to improve gas exchange in patients with ARDS with severe hypoxemia. Oxygenation improves in most adult patients with acute lung injury (ALI)/ARDS when they are placed prone.[104-107] A large, multicenter trial of prone positioning for almost 7 hours a day did not show improvement in mortality rates in patients with ALI/ARDS; however, a post hoc analysis suggested improvement in those patients with the most severe hypoxemia.[108] A recent multicenter trial of prone positioning for almost 20 hours a day also suggested improvement in this patient subgroup that did not reach statistical significance.[109] A recent Cochrane Review identified nine relevant RCTs that studied the effect of prone positioning for acute respiratory failure on outcomes.[110] While prone positioning resulted in a relative risk of less than 1, it was not statistically significant when all patients were included. Early implementation of PP, prolonged adoption of PP, and severe hypoxemia at study entry were three subgroups that showed a statistically significant mortality benefit.[111-117]

Bruno et al.[118] reported the short-term effects of 1 to 2 hours of prone positioning in children with respiratory failure. They found that only 28% of the patients had a significant improvement in oxygenation.[118] Curley et al.,[119] in a preliminary single-center study in children with ALI/ ARDS, showed that oxygenation improved with prone positioning in 84% of patients without any critical incident. Relvas et al.[120] also reported a retrospective study on the effects of prone positioning in children with ARDS and showed that the improvement in oxygenation was much more sustained if the duration of prone positioning was between 18 and 24 hours than when the

duration of prone positioning was between 6 and 10 hours.[120] A recent multicenter study on prone positioning in children with ALI/ARDS showed that patient recruitment within 48 hours of meeting acute lung injury criteria and prone positioning for 20 hours a day for a maximum of 7 days did not show any differences in the number of ventilator-free days between the two groups.[121] There were no differences in the secondary end points, including proportion alive and ventilator free on day 28, mortality from all causes, the time to recovery of lung injury, organ failure–free days, and cognitive impairment or overall functional health at hospital discharge.[121]

Although the magnitude of the response varies widely from marginal to dramatic, there is no adequate model predicting where a particular patient with ARDS will fall in the spectrum. Furthermore, patients' response times vary from immediate to several hours. As a result, little is known about the optimal time period to maintain the prone position. Some patients respond to a return to a supine position after a trial of prone positioning by reverting to their original oxygenation, others have a reduction in oxygenation that is better than the original supine value, and some patients show an improvement. Prone positioning may have potentially life-threatening complications, including accidental dislodgement of the endotracheal tube and central venous catheters. Marcano et al.[122] reported that prone positioning resulted in cephalad movement of the endotracheal tube within the trachea in children with ARDS ranging from 10% to 57% of their thoracic tracheal length. Their study also suggested that if the tip of the endotracheal tube is not deeper than one-third of the thoracic tracheal length before prone positioning, it might slide into the cervical trachea as a result of prone positioning.[122]

Unilateral Lung Disease or Severely Differential Lung Disease

Unilateral or asymmetrical lung disease in infants and children poses special problems during mechanical ventilation. Some of these patients may have severe intrapulmonary shunts leading to hypoxemia requiring mechanical ventilation. Because of regional differences in compliance and resistance, the time constants for inflation and deflation may vary widely between lung segments. During conventional ventilation, tidal volume delivered tends to preferentially inflate the more compliant lung and underventilate the stiffer, more affected lung. This may result in overinflation of the relatively “normal” lung and cause redistribution of pulmonary blood flow away from the hyperinflated lung, thus exaggerating the ventilation-perfusion mismatching. Such overinflation may contribute to further barotrauma. In such circumstances, with unilateral or asymmetrical lung disease, simultaneous independent lung ventilation (SILV) may allow each lung to be ventilated according to its needs without affecting the opposite lung. Currently, SILV can be generally indicated in the treatment of unilateral lung disease, such as unilateral atelectasis or consolidation, emphysema, pneumonia, pneumothorax, and bronchopulmonary fistula. In postoperative care, ILV can be used for lung reexpansion after thoracic surgery, for correction of V/Q mismatch in the lung remaining dependent during surgery, and for the treatment of pulmonary complications arising during anesthesia and surgery (eg, pneumothorax or aspiration syndrome). A new possible indication for SILV can be the selective

administration of drugs to one lung, such as antibiotics or surfactant. SILV requires a bilumen tube with one tube being the longer “bronchial” tube and the other shorter “tracheal” tube. Usually, the bronchial tube is advanced into the right main stem bronchus so that both lungs can be ventilated separately.

In adults, SILV has been shown to be useful in the treatment of unilateral lung disease.[123-126] In infants and children, SILV has been limited because of the lack of a suitable bilumen tube. Marraro[127] reviewed their experience with SILV in infants and children younger than 1 year with a bilumen tube developed in their department, but it is currently available through Portex Ltd. (Mythe, Kent, United Kingdom). The indications included bronchopneumonia with unilateral prevalence, unilateral pneumonia, lobar atelectasis, and diaphragmatic hernia. Nine of 41 patients treated with SILV had rapid improvement in lung disease, whereas the other 32 recovered more slowly. No major complications were attributed to SILV. In newborns and infants, it is possible to provide ILV with a double-lumen endotracheal tube manufactured by Portex as special equipment. In children older than 6 to 8 years, selective bronchial intubation is possible using a cuffed double-lumen tube similar to that used in adults (26- to 28-Fr Bronchocath Mallinckrodt, Bronchoport Rusch). The Marraro Paediatric Endobronchial Bilumen Tube, produced by SIMS-Portex, may be used in neonates and children age 2 to 3 years.[128] It is uncuffed to maximize the internal diameter of the tube and has no carinal hook; this minimizes tracheal trauma.[107-109] ILV requires two ventilators that permit the application of different modes of ventilation and different PEEP levels for each lung. Synchronization of the beginning of the inspiratory phase and the inspiratory time can avoid mediastinal shifts that impede venous return and reduce cardiac output.[127-129]

Heart Failure

The goals in respiratory management in congestive heart failure are prevention and relief of alveolar collapse from alveolar and interstitial edema due to pulmonary vascular congestion, as well as decreased oxygen demand on the heart with a reduction in the work of breathing. CPAP/PEEP will provide relief of atelectasis. Hyperinflation should be avoided because it may increase pulmonary vascular resistance and increase right ventricular afterload. The oxygen cost of breathing can be reduced with a decrease in the work of breathing. This can be provided by a judicious combination of controlled ventilation and sedation. By unloading the respiratory muscles, mechanical ventilation can also reduce the work of breathing. In extreme cases, muscle relaxation by neuromuscular blockers may provide additional reduction in oxygen cost of breathing. As a general principle, the greater the inotropic support a heart needs, the greater should be the respiratory support provided. Tidal volumes should be generally maintained on the lower range (8–10 mL/kg). In adults with congestive heart failure, positive intrathoracic pressure has been shown to improve cardiac output.[130,131] This effect has been attributed to decreased left ventricular afterload provided by positive airway pressure.

Postoperative Management After Repair of Congenital Heart Disease

After open heart surgery, many infants and children require mechanical ventilation

during the postoperative period. The duration of requirement of mechanical ventilation depends on several factors such as age of the patient, complexity of the cardiac lesion, complexity of the operative procedure, duration of bypass, duration of circulatory arrest, and postoperative cardiopulmonary status. Prolonged intubation and mechanical ventilation are more likely in children younger than 1 year of age, with more complex heart lesions, prolonged bypass and prolonged circulatory arrest times, and postoperative respiratory failure and hemodynamic instability. In the immediate postoperative period, patients should be supported with controlled mechanical ventilation until hemodynamic functions improve. Adequate PEEP should be applied to prevent and relieve atelectasis. Initially, the ventilator rate should be appropriate for the age. As the hemodynamic function improves, the rate can be weaned, as dictated by the clinical status. The choice of ventilatory parameters depends on the goals for each patient. In patients with pulmonary hypertension or pulmonary vascular disease, hyperventilation to provide respiratory alkalosis will decrease pulmonary vascular resistance and right ventricular afterload. In patients with marginal cardiac output, high airway pressures are to be avoided. In patients who have undergone a Fontan procedure, early extubation is desirable, and if that is not possible, then spontaneous ventilation should be encouraged. Because these patients are totally dependent on venous return for their cardiac output, airway pressures must be kept at a minimum. High intrathoracic pressure may not only impede venous return but also decrease pulmonary blood flow from increased pulmonary vascular resistance.

Diseases With Abdominal Distention

The presence of abdominal distention poses a special problem. Positive intraabdominal pressure tends to elevate the diaphragm, decrease P_{tp} in the lung bases, and decrease alveolar lung volumes in the lung bases. For normal lung volumes to be maintained, a greater P_{tp} has to be generated. This increases the airway pressures during positive pressure ventilation and increases work of breathing during spontaneous breathing. During positive pressure ventilation, a higher P_{tp} may cause hyperinflation of the apical regions while restoring normal volumes in the bases. Therapy should be directed primarily toward reducing the intraabdominal pressure.

Neurologic and Neuromuscular Diseases

Hyperventilation with respiratory alkalosis is an effective method of reducing intracranial pressure. High intrathoracic pressure may impede venous return from the brain by increasing central venous pressures. Therefore high levels of PEEP are to be avoided. The goals of respiratory support in patients with acute neuromuscular diseases that are self-limiting are (1) provision of respiratory assistance to maintain adequate minute ventilation and (2) avoidance of disuse muscle atrophy from mechanical ventilation. Spontaneous breathing must be encouraged as much as possible. Neuromuscular blockade must be avoided.

Patient-Ventilator Asynchrony

One of the primary goals of mechanical ventilation is to reduce the patient's work of breathing. This can be achieved only if the patient's respiratory muscles and the ventilator act in a coordinated manner. The patient should not be attempting to inspire when the ventilator is in the expiratory phase and should not be attempting to exhale when the ventilator is attempting to deliver a breath. Patient-ventilator asynchrony is defined as a mismatch between the inspiratory times of the patient and the ventilator. Asynchrony can occur during intermittent mandatory ventilation, patient-triggered mandatory breaths, supported spontaneous breaths, and assist-control ventilation. It is important to recognize patient-ventilator asynchrony and take measures to either minimize or eliminate it.

A detailed description and analysis of patient-ventilator asynchrony is beyond the scope of this chapter, and the reader is referred elsewhere.[132-142] There are different types of asynchrony related to the different phases of breathing. The triggering phase is from onset of patient effort to onset of flow delivery.[138-142] The post-triggering inspiratory phase comprises the onset of flow delivery to the termination of machine inspiration. The cycling phase or expiratory triggering refers to the termination of machine inspiration and the onset of expiration. Brief summaries of the types of asynchrony in the different phases are described as follows.

Asynchrony Associated With Breath Triggering

It is important to first understand the different components of the trigger phase. Trigger threshold refers to the variable that determines the onset of a breath. The four common types of trigger mechanism available on commercial ventilators are time, pressure, volume, and flow. There is a fifth type called the shape-signal or "shadow" trigger that is available on the Respironics noninvasive ventilators.[141-143] For time triggering, the trigger threshold is a set interval of time from the previous breath; in pressure triggering, it is the minimum pressure decrease from PEEP; and in flow and volume triggering, it is the minimum change in flow or volume in the circuit that is sensed by the ventilator to initiate a breath. The inspiratory trigger time is the time elapsed between the initial patient effort and the point at which the airway pressure reaches the maximum baseline. Time to return trigger pressure to zero is the time taken after the ventilator is able to supply flow to returning the airway pressure to the pretrigger baseline. This is influenced by the rise time setting in the ventilator. Triggering time delay is the time from onset of triggering to the onset of flow delivery and is the sum of the inspiratory trigger time and the time to return trigger pressure to zero. Asynchrony associated with breath triggering can be classified into (1) missed triggering, (2) delayed triggering, (3) autotriggering, (4) double triggering, and (5) reversed triggering.

Missed triggering: Missed triggering refers to a spontaneous breath that is not accompanied by a synchronous assisted/supported mechanical breath. Missed triggering results in a patient's effort that fails to trigger a ventilator breath. This can be due to either poor patient effort or an insensitive threshold. Poor patient effort may result in a breath that is not strong enough to reach the trigger threshold. This may be due to muscle weakness that results in an effort that is below the trigger threshold. It may also be due to an increased load on the muscles at the start of inspiration such as induced by intrinsic PEEP, when the patient

effort is insufficient to trigger the breath. It can also be due to the trigger threshold being set too high (insensitive trigger). Ineffective triggering can be detected as a pressure drop in the airway with a change in flow but not followed by a ventilator breath. Ineffective triggering can be resolved by setting the trigger sensitivity low enough to capture the patient's efforts but not result in autotriggering (see later). On the other hand, the threshold may be set too high or may not sense the effort that results in a wasted spontaneous breath. Delayed triggering is defined as a lag from sensing the trigger to delivering the mechanical breath. Delayed triggering refers to the delay in the start of the ventilator breath after the patient's effort has been detected. This is usually intrinsic to the trigger sensitivity and electronic response of the ventilator circuit.

Autotriggering: When a breath is delivered neither in response to a scheduled event nor triggered by a patient effort, it is referred to as autotriggering. It is best detected with esophageal monitoring where a breath is delivered in the absence of a diaphragmatic contraction. Ventilator factors that are associated with autotriggering are a low triggering threshold, circuit leak, and water in the circuit. Patient-related factors include cardiac oscillation and low respiratory drive. Autotriggering is the most common type of patient-ventilator asynchrony during noninvasive ventilation, usually due to leaks around the interface.[144]

Double triggering: When two consecutive inspirations occur within an interval of less than half of the mean inspiratory time, it is referred to as double triggering.[141,142] The usual reason for double triggering is a mismatch between a neural inspiratory signal that is longer than the machine's inspiratory time. This results in the second breath being triggered after the first breath has been delivered. Double triggering can also occur when a pressure-supported breath has a high termination criterion.[142] These breaths may occur on top of each other or soon after each other.[141,142] When the breaths are stacked, the peak inspiratory pressure may be increased by the second breath. While missed trigger events are due to the low patient effort relative to the trigger threshold, double triggering is usually due to excessive patient demand or effort. Double triggering may also occur with sighs or coughing.[141,142]

Asynchrony During Inspiration (Flow Asynchrony)

Once the breath is initiated, the flow of gas into the patient must match the needs of the patient. When the patient's demand is met by the ventilator, the profile of the pressure-volume and pressure-time curves is more “physiologic.”[141] Most common form of flow asynchrony occurs when the patient's demand exceeds the delivered flow and is more likely to occur with acute respiratory failure from ARDS. The pressure-time curve in ventilator graphics display can be useful in assessing flow asynchrony. Less common is a delivered flow that is in excess of the patient's needs resulting in larger tidal volumes.

Asynchrony During Cycling

Cycling asynchrony occurs when the ventilator drive and cycling criteria are mismatched. Either the ventilatory drive is abnormal or the cycle criteria are set too

long or too short. With a high respiratory drive, cycling may occur sooner as the ventilator breath ceases abruptly. When the ventilator cycling occurs later than the patient's intrinsic cycling, machine cycling is prolonged. Delayed cycling refers to the prolongation of the ventilatory inspiration breath beyond the start of the patient's expiration. This can occur during pressure-support ventilation and can induce adverse effects such as increasing hyperinflation and intrinsic PEEP due to a shortened expiratory time. Premature cycling refers to the ventilator terminating inspiration while the patient is still continuing to have inspiratory efforts. This most commonly occurs in the presence of a leak in the ventilator circuit or around the endotracheal tube.

Ideally, ventilator breaths should be synchronized with spontaneous breaths. Asynchrony between mechanical ventilation and spontaneous breathing is common, especially in small infants. The most common form of asynchrony is active exhalation during a ventilator-delivered inspiratory breath. This has several detrimental effects. These are increased expiratory work of breathing, decreased overall minute ventilation with hypercarbia, patient discomfort, and increased risk for air leak.[145,146] Patients exhibiting asynchrony during mechanical ventilation have shown improved oxygenation and ventilation after neuromuscular blockade.[147,148]

Patient-ventilator asynchrony has been recently studied in infants and children mainly in the context of comparing NAVA with conventional modes.[77-79,149,150] These show a high prevalence of asynchrony. NAVA did decrease the overall magnitude of asynchrony but did not completely eliminate it.[77-79,149,150] Two recent studies show that asynchrony events are frequent during pressure-support ventilation in children during both invasive and noninvasive ventilation.[151,152] Despite adjusting the cycling-off criteria, the asynchrony persisted. NAVA reduced the magnitude of asynchrony significantly in both forms of ventilation.

Use of Neuromuscular Blockade

Neuromuscular blockers are often used as adjunctive therapy to mechanical ventilation. Although spontaneous breathing is to be encouraged as much as possible, respiratory muscle paralysis becomes necessary at times as an aid to mechanical ventilation. The indications for the use of neuromuscular blocking agents during mechanical ventilation are (1) asynchrony between the patient and ventilator; (2) use in controlled ventilation; (3) a decrease in oxygen demand of skeletal muscles, especially in patients with hemodynamic instability; and (4) prevention of coughing, especially in patients with intracranial hypertension. Neuromuscular blockade is also used in patients when ventilation is to be controlled so that the appropriate minute ventilation is delivered. Paralysis of respiratory muscles may also be required in patients after congenital heart surgery to reduce the oxygen demand on the heart. Prolonged neuromuscular blockade is to be avoided because it tends to promote muscle atrophy. This, in turn, will prolong weaning from mechanical ventilation.

High-Frequency Ventilation

Definitions

High-frequency ventilation (HFV) refers to diverse modes of ventilation characterized in general by supraphysiologic ventilatory frequencies (>60 cycles/min) and low tidal volumes (less than or equal to physiologic dead space during conventional ventilation). Four distinct methods of HFV are recognized: high-frequency positive pressure ventilation (HFPPV), high-frequency jet ventilation (HFJV), high-frequency oscillatory ventilation (HFOV), and high-frequency chest wall oscillation (HFCWO).

1. HFPPV: HFPPV was first described by Oberg and Sjostrand in 1969[153] and refers to ventilation at a frequency of 60 to 100 cycles per minute with a tidal volume of 3 to 4 mL/kg using a ventilator with a small internal dead space, low internal compliance, and minimal compression of gases within the ventilator. HFPPV was initially instituted by insufflation through a catheter positioned within the endotracheal tube, with expiration occurring through an expiratory valve connected to the outer orifice. Since 1973, a pneumatic valve, based on the Coanda or wall effect, was developed in which the gas mixture was intermittently delivered through a sidearm branching off the main channel of the pneumatic valve connector (Fig. 57.19).

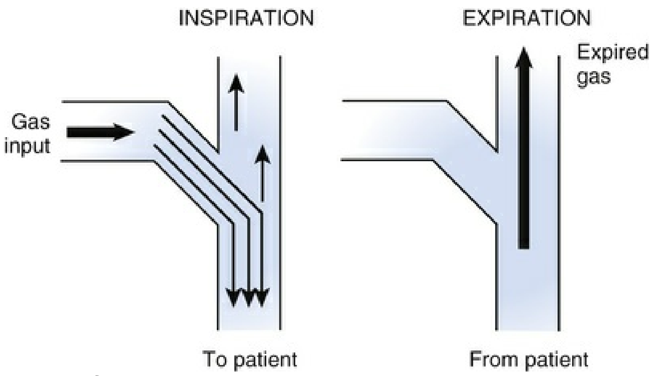

FIG. 57.19 High-frequency positive pressure ventilator. The inspiratory limb is angled so that the inspiratory gas can be directed to the patient. During inspiration, some gas escapes through the expiratory limb, preventing entrainment. During expiration, the gas flows out into the expiratory limb. (Reproduced with permission from Shoemaker WC, Ayres S, Grenvik A, et al., eds. The Textbook of Critical Care. Philadelphia: WB Saunders; 1989.)

This main channel remains open for insertion of a bronchoscope or a laryngoscope.

2. HFJV: HFJV, which was first described by Sanders in 1967[154] to assist bronchoscopy, refers to delivery of inspiratory gases through a jet injector at a high velocity into the trachea at a rate of 100 to 400 cycles per minute (Fig. 57.20). Tidal volumes delivered are usually 3 to 5 mL/kg.

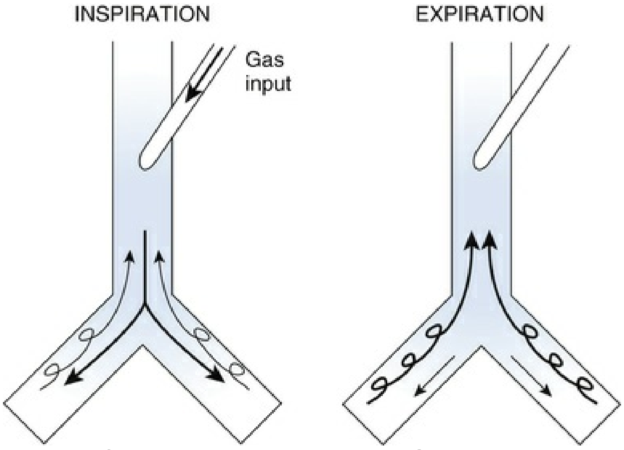

FIG. 57.20 High-frequency jet ventilator. Gas is introduced into the trachea at a high pressure through a small catheter. *Arrows* represent coaxial and turbulent flow patterns. (Reproduced with permission from Shoemaker WC, Ayres S, Grenvik A, et al., eds. The Textbook of Critical Care. Philadelphia: WB Saunders; 1989.)

3. HFOV: HFOV was first described by Lunkenheimer in 1972[155] and refers to ventilation at frequencies of 900 to 3600 cycles per minute, with an alternating positive and negative pressure in the airway. This oscillatory flow may be produced by a piston pump or a diaphragm with tidal volumes of 1 to 3 mL/kg (Fig. 57.21).

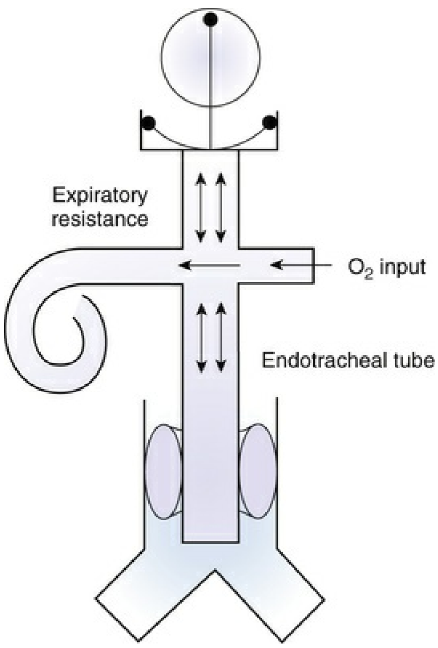

FIG. 57.21 High-frequency oscillation system. Uses a reciprocating pump *(top)* to oscillate a column of gas that is a mixture of inspired and expired gases. Excess gas is vented through the overflow side port *(left)*. (Reproduced with permission from Shoemaker WC, Ayres S, Grenvik A, et al., eds. The Textbook of Critical Care. Philadelphia: WB Saunders; 1989.)

4. HFCWO: HFCWO was first described by Zidulka et al.[156] in 1983 and refers to a method of ventilation in which a rigid harness surrounds the chest and is oscillated

at a frequency of 180 to 600 cycles per minute; minute ventilation is controlled with adjustment of the inflation pressure and frequency. A variant of HFCWO is high-frequency body surface oscillation (HFBSO), in which the body is encased in an air-tight tank.

Only HFPPV, HFJV, and HFOV have been extensively used clinically.

Mechanism of Gas Flow in High-Frequency Ventilation in the Normal Lung

The exact mechanism of gas transport in HFV is currently not clear. It is possible that each mode of ventilation may have differing mechanisms of gas flow from the proximal airway to the alveoli. If gas flow to the lungs is increased more than 200 times the minute volume of oxygen demand, the lung parenchyma can be made to oscillate.[157,158] At ventilatory frequencies less than 7 Hz, regional alveolar ventilation depends on segmental compliance and airway resistance. At a ventilatory frequency greater than 7 Hz, a frequency-dependent excitation of the lung parenchyma and airway conduits occurs,[159] and at frequencies greater than 10 Hz, ventilation becomes independent of regional compliance. When the gas in the airways is oscillated at high frequency, the airways begin to undergo spatial oscillation inside the chest. These oscillations are composed of periodic changes in length and width, movements of curved or angular bronchi, and wave motions in the bronchi. When the frequency of oscillation approaches the natural resonant frequency of the lung structures, the oscillations of the airways and lung parenchyma are amplified. These result in shaking and squeezing of the neighboring parenchyma, resulting in intraparenchymal and interparenchymal gas mixing.[160] Other mechanisms involved in gas transport during HFV include accelerated axial dispersion, increased collateral flow through pores of Kohn, intersegmental gas mixing or Pendelluft phenomenon, Taylor dispersion, asymmetric gas flow profiles, and gas mixing within the airway due to the nonlinear pressure-diameter relationship of the bronchi.

Parameters to Be Selected

High-Frequency Jet Ventilation

The main controls in HFJV are the driving pressure, inspiratory time, and rate. The driving pressure is usually initiated at a desired mean airway pressure and adjusted according to the level of lung expansion and gas exchange. Inspiratory time is usually kept to a minimum at 20%. A higher inspiratory time may be used but may result in air trapping. The rate can be adjusted up to 600 breaths per minute depending on the jet ventilator used. PEEP is applied through a separate bias flow circuit with continuous flow. FiO_2 delivered to the patient is adjusted through regulation of the inspired oxygen concentration of the bias flow circuit. In certain circumstances, conventional ventilation can be combined with HFJV. Here, conventional ventilation provides “sigh breaths” of approximately 10 to 12 mL/kg to prevent atelectasis and maintain lung volumes during HFJV. The size of each breath increases with a higher driving pressure, increased inspiratory time, and a decreased frequency. Because there is entrainment of gas with HFJV, it is difficult to predict the effect of ventilator parameters on minute ventilation. Ventilation is most effective

when the jet catheter is close to the carina. The main concerns with HFJV are airway injury and air trapping. Airway injury can be minimized with placement of the tip of the catheter sufficiently proximal in the endotracheal tube and without close placement close to the carina. Air trapping can be avoided with the minimal inspiratory time and the lowest driving pressure.[161]

High-Frequency Oscillatory Ventilation

Currently, the HFOV systems available in North America are the Viasys Critical Care 3100A and 3100B ventilators. The main difference between the two ventilators is the age range each of them supports. The 3100A is designed to support HFOV in neonates and small children. The 3100B is designed to support older children and adults weighing more than 35 kg. Input power for both the ventilators requires two pneumatic gas sources and one electrical source. The first pneumatic connection through a blender determines the FiO_2 delivered to the patients. The second pneumatic connection is for cooling the oscillator. The drive mechanism is a square-wave driver, which has an electric linear motor and a piston. The stroke of the piston (both positive and negative) determines the amplitude. The position of the piston determines the mean airway pressure of the circuit.

The main controls in HFOV are mean airway pressure, oscillatory pressure amplitude, bias flow, frequency, and inspiratory time. With piston-driven oscillators, piston-centering is an additional control mechanism. Mean airway pressure determines the mean lung volume of the lung. Oscillatory amplitude is the total change in pressure around the mean airway pressure produced by forward and backward displacement of the piston. The pressures developed in the patients' airways are considerably dampened because of the impedance of the endotracheal tube. Similarly, the pressure profile is further dampened in the distal airways because of the impedance of the proximal airways. If the oscillatory frequency approaches the natural resonant frequency of the lung and airways, then there may be amplification of the pressure waves. The oscillatory amplitude determines the volume displacement with each stroke of the piston. If the volume of gas displaced is less than the dead space of the airways and lungs, then there is little chest displacement. If sufficient chest displacement is seen with each stroke, then the volume of gas displaced tends to be larger than the physiologic dead space and results in some direct alveolar ventilation. Frequency is the next parameter that can be controlled and is usually in the range of 5 to 10 Hz. For a given amplitude, a lower frequency will result in less attenuation of pressures along the airways and improve gas exchange. Inspiratory time is generally controlled at 33% of the total cycle time. In certain circumstances a lower inspiratory time may be used. Bias flow is a continuous flow of fresh humidified gas and allows replenishing oxygen and removing carbon dioxide from the circuit. Determinants of oxygenation during HFOV are mean airway pressure and FiO_2. Minute ventilation during HFOV is directly proportional to the frequency and the square of the tidal volume. Tidal volume is determined by the amplitude and the duration of each stroke. With increased frequency, the time for each stroke is reduced, decreasing the tidal volume. When the ventilatory frequency is decreased, this increases the time for each stroke and thereby increases the tidal volume. The primary determinant of ventilation is oscillatory amplitude. Decreasing the frequency to reduce attenuation

and increasing the inspiratory time are less effective strategies to improve carbon dioxide elimination.

High-Frequency Percussive Ventilation

High-frequency percussive ventilation (HFPV), a newer mode introduced during the past 20 years, combines the beneficial effects of HFV with conventional ventilatory support.[162-164] HFPV has been described as an exceptionally versatile form of HFV that delivers subphysiologic tidal volumes at rapid rates (up to 500 breaths/min) using the volume-diffusive respirator.[162-164] It has been shown to provide the same or improved oxygenation and ventilation at lower peak, mean, and end-expiratory pressures when compared with conventional ventilation.[162-164]

The high-frequency percussive ventilator (Percussionaire, Bird Technologies, Sandpoint, Idaho) is a pneumatically powered, time-cycled, and pressure-limited ventilator with inspiratory and expiratory oscillation. The ventilator is connected to a high-pressure flow generator, fed by an air-oxygen blender. Two inspiratory circuits come off the ventilator—one a high-pressure and the other a low-pressure circuit. The low-pressure circuit is connected to the humidifier and a nebulizer system. The humidifier and nebulization system provide a gas mixture that is appropriately heated and fully humidified. The high-pressure circuit is a low-compliant tubing. Both the circuits attach to a system called the “Phasitron,” which is a sliding Venturi that acts as both an inspiratory and expiratory valve. The Phasitron is driven by a high-pressure gas supply at a high-frequency rate of 200 to 900 beats/min superimposed on a conventional inspiratory/expiratory pressure-controlled cycle that is set at a desired rate. From the Phasitron, there are two branches: an inspiratory limb that attaches to the endotracheal tube and an expiratory limb. The Phasitron consists of a hollow cylinder in which there is a spring-controlled piston driven by the high-pressure circuit. Two safety valves, one inspiratory and one expiratory, regulate the pressure delivered to the airway. There are seven control variables: (1) peak inspiratory pressure, (2) positive end-expiratory pressure, (3) continuous positive airway pressure, (4) inspiratory time, (5) expiratory time, (6) percussive frequency, and (7) rate. The tidal volume delivery is a product of the peak inspiratory pressure (PIP) setting and subtidal volumes produced by the oscillatory function. During inspiration, lung volumes are progressively increased in a controlled, stepwise fashion by repetitively diminishing subtidal volume deliveries until an oscillatory plateau is entered and maintained. At the end of inspiration, the lung is allowed to empty passively until the preset expiratory baseline is reached. Gas exchange has been noted to be as good, if not better, than CV at lower airway pressures. The endotracheal tube cuff should be left partially deflated to allow for a continuous air leak through the trachea.

Clinical Uses of High-Frequency Ventilation

The principal theoretical advantage for the use of HFV lies in the ability to ventilate effectively at low airway pressures. The most common use of HFV is in the operating room for use in airway operations; in laryngoscopies; in bronchoscopies; and in emergency airway management, in which airway movement has to be reduced to a minimum.[161] HFV has been used to manage neonates with idiopathic respiratory distress syndrome with the goal of decreasing the incidence of pulmonary

barotrauma. Initial studies showed improvement in gas exchange with lower airway pressures, provided periodic sigh maneuvers were performed.[165-168] HFV has also been shown to support adequate gas exchange with severe pulmonary interstitial emphysema (PIE) in neonates.[169,170] The initial enthusiasm for HFOV as a method for reducing pulmonary barotrauma in premature neonates with idiopathic respiratory distress syndrome requiring mechanical ventilation has been tempered by a recent multicenter trial in which HFOV did not prove to be superior to conventional mechanical ventilation.[171] One area of relatively proven benefit of HFV is in the management of bronchopleural fistulae. HFJV has proven useful in the management of bronchopleural fistula, with consistent improvement in arterial blood gas, when conventional ventilation had previously failed.[172] Recent studies have suggested a role for HFV in children after cardiac surgery and with ARDS.[173-178] HFJV has been shown to improve cardiac function after a Fontan procedure.[173] HFJV and HFOV have been shown to improve oxygenation and ventilation compared with conventional ventilation in children with respiratory failure.[175-178] Our results indicate that high-frequency oscillatory ventilation, utilizing an aggressive volume recruitment strategy, results in significant improvement in oxygenation compared with a conventional ventilatory strategy designed to limit increases in peak airway pressures. In a prospective study of HFOV compared with conventional ventilation, HFOV resulted in improved oxygenation, lower requirement for supplemental oxygen at 30 days, and improved outcome compared with conventional mechanical ventilation.[178]

The most common approach to HFOV in infants and children is as a rescue therapy when conventional mechanical ventilation proves to be insufficient to recruit the lungs and maintain adequate gas exchange. There are many reported strategies with the use of HFV: (1) "high lung volume strategy," which requires HFV to be provided at a mean airway pressure that is at least 3 to 5 cm higher than with conventional ventilation; (2) combined HFV and conventional ventilation (usually used with HFJV), in which conventional tidal breaths are interposed during HFV usually at a rate of 5 to 8 breaths per minute; or (3) application of HFV at the same mean airway pressure as conventional ventilation. The high lung volume strategy seems to be the most promising one at least for HFOV. When transitioning the patient to HFOV from conventional ventilation, the mean airway pressure on HFOV is set to 3 to 6 cm H_2O above the mean airway pressure on conventional ventilation. It is important to recruit the lung before placing the patient on HFOV. Amplitude is set by adjusting the power control while observing for adequacy of chest wall vibrations. The goal for oxygenation is to employ a mean airway pressure that will allow reduction of FiO_2 to at least 0.6 while maintaining an arterial oxygen saturation of at least 90%. This may require titrating the mean airway pressure from the initial setting. Adequacy of lung recruitment is usually verified by ensuring that both hemidiaphragms are displaced to the level of the ninth posterior rib on a chest radiograph. Once an appropriate degree of lung inflation and patency of the endotracheal tube are verified, ventilation needs to be addressed. Arterial $PaCO_2$ can be maintained at the desired level by changing the amplitude or frequency. Ventilation is increased by an increase in amplitude and a decrease in frequency. It is also important to deflate the cuff of the endotracheal tube, if a cuffed tube is used. Adjusting the bias flow can also aid in ventilation but is seldom done in routine

clinical practice.

Case series in neonates with respiratory failure showed that HFPV can result in improvement in oxygenation and ventilation with a reduction in FiO_2 and PEEP requirements.[179-181] One other purported advantage to high-frequency percussive ventilation is the mobilization of secretions. This has generated much interest from the burn community, particularly for the treatment of children and adults with inhalation injury.[182-188] Two prospective, randomized trials of HFPV have been reported in the pediatric burn population. Compared with the conventional ventilation, high-frequency percussive ventilation resulted in similar ventilation and improved oxygenation at significantly lower peak inspiratory pressures. Pneumonia and mortality rates were lower in the high-frequency group.[183,184]

Adverse Effects of Mechanical Ventilation

Yin-Yang of Mechanical Ventilation

Mechanical ventilation has profound effects on various organ systems; some are beneficial and others have adverse effects. The beneficial and adverse effects can occur simultaneously; the net effect of mechanical ventilation results from the interaction of useful and deleterious effects. The beneficial effects in the lung are related to improvements in pulmonary mechanics and gas exchange. Adverse effects of positive pressure ventilation are related to (1) consequences of positive intrathoracic pressure and (2) injury to the airway. Some of the important adverse effects of mechanical ventilation are shown in Table 57.5.

TABLE 57.5

Adverse Effects of Mechanical Ventilation

Respiratory system
Airways
Mucosal swelling
Ulceration
Granuloma formation leading to airway obstruction
Infection
Lung
Infection
Adverse effects on gas exchange
Effects on extravascular lung water
Air leaks
Cardiovascular system
Heart
Decreased venous return
Decreased left ventricular compliance
Decreased left ventricular afterload
Pulmonary circulation
Compression of alveolar vessels
Increased pulmonary vascular resistance
Other systems
Decreased renal blood flow
Decreased hepatic blood flow
Decreased cerebral venous drainage

Airway Injury

The presence of an endotracheal tube traversing the upper airway can be associated

with significant airway injury. Oropharyngeal and nasopharyngeal injuries are rare. Ulceration of the ala nasi from pressure necrosis may occur following prolonged nasotracheal intubation, particularly if the skin perfusion of the ala nasi is compromised by tight taping. Similar ulceration may occur at the angles of the mouth from tight taping of orotracheal tubes.[200,201] Palatal grooves and traumatic cleft palate can occur in infants.[202] Laryngeal injury may extend from minor swelling to ulceration of the mucosa of the vocal cords and aryepiglottic folds. Similarly, injuries in the subglottic region may extend from minor swelling to major ulceration. Healing of the severe injuries may lead to scarring or granuloma formation with airway obstruction, which may be partial or complete. The majority of the subglottic tracheal lesions is due to compression of the tracheal mucosa by the endotracheal tube. High-pressure cuffs, cardiovascular instability, upper respiratory tract infection, duration of intubation, and head-neck movement all increase the risk of tracheal injury. Airway injury can also result from suction catheters.[192] Necrotizing tracheobronchitis is a severe form of airway injury seen in patients on mechanical ventilation, which is characterized by extensive ulceration and mucosal damage. The sequelae of tracheal injuries include tracheal stenosis, tracheomalacia, tracheoesophageal fistula, and tracheoinnominate artery fistula.

Injury to the airway can be prevented by attention to several details. The endotracheal tube should be of the proper size, with a gas leak around it at less than 20 cm H_2O positive pressure. Excessive pressure on the skin should be avoided while taping of the endotracheal tube. Excessive patient movement should be prevented by adequate sedation and restraints. Endotracheal tube cuffs should be inflated with pressures less than 20 cm H_2O. Suctioning should be gentle, preferably with a catheter with multiple side holes. Suction catheters should not be routinely advanced beyond the tip of the endotracheal tube.

Effects on the Lung

Adverse effects of mechanical ventilation on the lung are due to the following factors: (1) high airway pressures, (2) overdistention of the alveoli, (3) altered mucociliary clearance, (4) lung water clearance, and (5) oxygen toxicity. The adverse effects of positive pressure ventilation may be manifested as (1) parenchymal injury, (2) altered ventilation-perfusion relationship leading to impaired gas exchange, and (3) increased risk for infection. Increased airway pressure may cause hyperinflation of the alveoli and predispose to alveolar rupture. Hyperinflation may increase alveolar dead space, impair cardiac filling, and compress alveolar vessels. "Pulmonary barotrauma" is a loose term that encompasses many entities of parenchymal injury. Alveolar rupture from overdistended alveoli is the most common manifestation of pulmonary barotrauma. Air leak may occur from the lung into the pleura (pneumothorax), interstitium (pulmonary interstitial emphysema, PIE), mediastinum (pneumomediastinum), pericardium (pneumopericardium), peritoneal cavity (pneumoperitoneum), and subcutaneous tissue (subcutaneous emphysema). Even though the term implies high airway pressures as the main mechanism of parenchymal injury, pulmonary barotrauma is often multifactorial.[193-196] The physiologic consequences of extra-alveolar air may range from no adverse effect to life-threatening cardiorespiratory compromise. A pneumothorax may be small and inconsequential or may be large and under tension. Tension

pneumothorax would need immediate evacuation of the pleural air. PIE may decrease lung compliance and increase pulmonary vascular resistance.[197] Pneumomediastinum requires careful observation. The natural tendency of pneumomediastinum is to track along fascial planes either cephalad to produce subcutaneous emphysema or caudad to produce pneumoperitoneum or pneumoretroperitoneum. Pneumomediastinum rarely requires evacuation. Pneumopericardium can range from a minimal inconsequential amount of air to life-threatening cardiac tamponade. Cardiovascular compromise is an indication for immediate evacuation of pericardial air.

A special form of pulmonary air leak is a bronchopleural fistula, where a fistulous track develops between the bronchus and the pleural space. This results in an almost continuous flow of air from the airway into the pleural space. The fistula flow is wasted ventilation and may result in hypercarbia. Attempts to increase minute ventilation by increasing tidal volume will only serve to increase the fistula flow by increasing the pressure gradient across the fistula. If attempts to decrease airway pressures with conventional ventilation are not possible without compromising gas exchange, a trial of high-frequency ventilation may be tried.

Barotrauma can be minimized by avoiding factors that predispose to pulmonary air leakage. The principal factors that can be controlled are airway pressures and lung volumes. As long as acceptable gas exchange is maintained, every effort must be made to reduce airway pressures to a minimum. Hyperinflation must be avoided. When the lung disease is severe, deliberate hypercarbia may be tolerated provided the arterial pH is normal. Inspired oxygen concentration should be maintained at nontoxic levels (usually <50%).

Effects on Circulatory System

The cardiovascular effects of positive intrathoracic pressure are complex and depend on the underlying lung disease, uniformity of lung disease, transmission of airway pressure to the pleural space, lung volume, etc. Cournand's laboratory was one of the first to demonstrate that positive pressure ventilation decreased cardiac output.[198,199] Positive intrathoracic pressure impedes right ventricular filling by decreasing the pressure gradient to venous return.[198-201] Positive airway pressure also increases pulmonary vascular resistance, provided the airway pressure exceeds left atrial or critical closing pressure.[202] Positive intrathoracic pressure has also been shown to decrease left ventricular afterload. The net effect is a combination of all the effects mentioned earlier and the reflex cardiovascular adjustments that accompany these changes. Positive pressure breathing also decreases urine output, and decreases hepatic, portal venous, and mesenteric perfusion.[203-207] Many of these effects can be offset by volume loading.

Specialty Gases

Altering Inspired Oxygen and Carbon Dioxide Concentration

A low alveolar oxygen tension increases pulmonary vascular resistance (hypoxic pulmonary vasoconstriction), and a high alveolar oxygen tension decreases

pulmonary vascular resistance.[208] With certain types of congenital heart disease such as hypoplastic left heart syndrome, it is critical to control pulmonary blood flow and prevent pulmonary overcirculation. One approach is to decrease the FiO_2 to less than 0.21 with a blending of room air with nitrogen. The exact FiO_2 delivered must be monitored to avoid administering excessively low inspired oxygen. Several studies have shown that hypoxic gas mixtures can be used both preoperatively and postoperatively to balance the pulmonary and systemic circulations.[209-211]

The other approach, especially in patients undergoing mechanical ventilation, both preoperatively and postoperatively, is to increase the inspired carbon dioxide concentration ($FiCO_2$). Increased $FiCO_2$ also increases pulmonary vascular resistance. During mechanical ventilation, increased $FiCO_2$ allows one to hyperventilate and prevent atelectasis without producing hypocarbia. One of the difficulties with a boost in $FiCO_2$ is increased spontaneous ventilatory drive due to an increased $PaCO_2$. This increases the work of breathing and with marginal cardiac reserve may impose undue strain on the heart. Therefore in spontaneously breathing patients, neuromuscular blockade and total ventilatory support may be necessary with increased $FiCO_2$ to avoid an increased workload on the heart. Morray et al.[212] were the first to report on this technique to increase PVR to prevent pulmonary overcirculation. This finding has been confirmed in both an experimental model[213] and in infants with hypoplastic left heart syndrome.[214]

Helium-Oxygen Mixture

Helium-oxygen mixture has much lower density compared with oxygen-nitrogen mixture and offers a reduced resistance to breathing.214a A detailed description of the properties of helium-oxygen mixture and its clinical applications is beyond the scope of this chapter, and the reader is referred to excellent reviews on this topic.[215-221] On the basis of the physics of airflow and the properties of heliox, the behavior can be predicted with its use. The predictions are (1) heliox will result in a higher flow when transairway pressures are held constant, (2) heliox will result in a lower airway pressure when the airflow is constant, (3) density-dependent flow meters will underestimate flow, (4) heliox can decrease the degree of air trapping and hyperinflation associated with lower airway obstruction, (5) heliox can decrease the work of breathing, and (6) heliox can result in better deposition of aerosols administered with it.[221] Helium is usually administered in at least 30% to 40% oxygen through a tight-fitting facemask. Use of an Oxyhood is not indicated because helium tends to separate and layer at the top of the Oxyhood with the patient breathing little helium.

Several studies have shown that heliox administration improves symptoms and relieves the respiratory distress associated with upper airway obstruction due to viral croup, subglottic narrowing, and postextubation stridor.[222-231] The use of heliox in asthma is increasing. It is being used as the carrier gas for bronchodilator aerosols, as well as continuously to relieve lower airway obstruction in status asthmaticus.[232-244] Most of the studies show improvement in clinical scores of respiratory distress, relief of wheezing, and faster resolution of symptoms.[232-244] It is important to remember that the quality of the breath sounds may be altered by heliox and may appear diminished due to the effect on airflow in the lungs. The patient may have

relief of symptoms while having a "silent chest" during heliox administration, and this may not be an ominous sign. It is important to auscultate the chest by discontinuing the heliox to appreciate if the lower airway obstruction and wheezing are still present. Heliox has also been used in acute bronchiolitis with or without positive airway pressure.[245-253] Similar to the studies in asthma, there is improvement in the clinical score and work of breathing in these infants.[245-253] Recently, helium-oxygen mixture has been shown to improve gas exchange in neonates with respiratory distress syndrome.[254] Oxygenation should be monitored during administration of helium-oxygen mixture to avoid hypoxia, especially in neonates.[255]

Inhaled Nitric Oxide

Inhaled nitric oxide produces selective pulmonary vasodilation. Indications for inhaled nitric oxide include diaphragmatic hernia, pulmonary hypertension after repair of congenital heart disease, primary pulmonary hypertension, and isolated right heart failure. In babies with severe hypoxemia and pulmonary hypertension, inhaled nitric oxide rapidly increases arterial oxygen tension without causing systemic hypotension.[256-259] Randomized controlled studies showed that nitric oxide inhalation safely improves arterial oxygen levels and decreases the need for extracorporeal membrane oxygenation (ECMO) therapy.[256-259] Oxygenation improves in approximately 50% of infants receiving nitric oxide. In addition, Kinsella and Abman[260] showed that high-frequency ventilation seems to augment the response to inhaled nitric oxide probably by better recruitment of alveoli. In children with ALI/ARDS, Ream et al.[261] showed an improvement in oxygenation in more than two-thirds of the patients. Researchers of a randomized controlled trial of inhaled nitric oxide in children with acute hypoxemic respiratory failure have also reported an improvement in oxygenation.[262] Results from several adult studies, however, showed that several participants failed to show any improvement.[263-266] In these multicenter studies in children and adults, there were no differences in ventilator-free days and no effect on mortality between treatment groups. Not all patients respond to inhaled nitric oxide. It seems prudent to test whether a patient will respond to inhaled nitric oxide. At Children's Hospital of Pittsburgh, a 2-hour trial of inhaled nitric oxide with 20 to 40 ppm is administered to infants and children with ALI/ARDS with hypoxemic respiratory failure. A good response is defined as improvement in PaO_2/FiO_2 ratio of greater than 100%. A partial response is defined as an improvement in PaO_2/FiO_2 ratio between 50% and 100%. If the response is less than 50%, the patient is considered a nonresponder. Inhaled nitric oxide is then continued in only those patients who show a partial or good response. Nitric oxide binds to hemoglobin to produce methemoglobin. Therefore methemoglobin levels should be monitored during administration of nitric oxide. In addition, nitric oxide combines with oxygen to form nitrogen dioxide. Nitrogen dioxide is known to cause lung injury. Therefore the concentration of nitrogen dioxide should be monitored in the inspired gas to keep it below 1 to 2 ppm.

Respiratory Care During Mechanical Ventilation

Pulmonary Hygiene

The primary objectives of airway clearance therapy are (1) to prevent and treat atelectasis from mechanical obstruction of airways and (2) to remove toxic substances including infective materials, proteolytic enzymes, and other mediators of inflammation.[267] Various airway clearance techniques have been reviewed recently and describe the evidence underlying each one of the techniques in children with and without neuromuscular disease.[268,269] On the basis of all these studies, it appears that the most effective method of clearing secretions is a combination of changing body position and vigorous coughing by the patient.[270] When the patient is unable to cough effectively, it is common practice to resort to chest physiotherapy and active suctioning of the trachea. Suctioning the trachea usually requires disconnecting the patient from the ventilator, passage of a suction catheter into the endotracheal tube, and application of suction to the catheter while the catheter is withdrawn from the endotracheal tube. In patients with marginal oxygenation, suctioning may result in hypoxia; arrhythmias; hemodynamic instability; and, in rare instances, cardiac arrest.[271-273] This can be prevented by prior hyperoxygenation. Suctioning may also result in cardiac arrhythmias. Chest physiotherapy refers to a variety of respiratory maneuvers performed to aid in the clearance of airway secretions and promoting lung expansion. These are (1) postural drainage, (2) chest percussion and chest vibration, and (3) deep breathing exercises. The efficacy of chest physiotherapy in patients who have undergone intubation is unclear. In adults, some studies have shown a benefit when all the components of the chest physiotherapy regimen are performed.[274] In children with cystic fibrosis, no additional benefit was provided by chest physiotherapy maneuvers when compared with spontaneous coughing.[275] Recently, several devices have been proposed as an adjunct to the standard chest physiotherapy. They include an intrapulmonary percussive ventilator (IPV); a mechanical insufflator-exsufflator (CoughAssist); the FLUTTER mucus clearance device and Acapella devices; intermittent positive pressure breathing (IPPB); mechanical percussors; and the ABI Vest, formerly known as the ThAIRapy Vest. The IPV is used in mechanized chest physical therapy; the IPV device delivers high-flow jets of air to the airways by a pneumatic flow interrupter at a rate of 100 to 300 cycles per minute through a mouthpiece. The patient controls variables such as inspiratory time, peak pressure, and delivery rates. Initial studies showed that in children with cystic fibrosis, IPV was as effective as standard aerosol and chest physiotherapy.[276,277] IPV was recently reported to improve atelectasis in children, compared with conventional chest physiotherapy.[278] A more recent study suggests that IPV may be more beneficial in secretion clearance in children with cystic fibrosis.[279] The mechanical insufflator-exsufflator (CoughAssist) is a portable electric device that uses a blower and a valve to alternately apply a positive and then a negative pressure to a patient's airway to assist the patient in clearing retained bronchopulmonary secretions. This device attempts to simulate a cough. Air is delivered to and from the patient through a breathing circuit incorporating a flexible tube; a bacterial filter; and a facemask, a mouthpiece, or an adapter to a tracheostomy or endotracheal tube. Miske et al.[280] reported that in children with neuromuscular disease and impaired cough, the use of a mechanical insufflator-exsufflator was safe, well tolerated, and effective in preventing pulmonary complications. The FLUTTER mucus clearance device and Acapella device are small handheld devices that provide positive expiratory pressure (PEP.) Exhaling through the device creates oscillations, or “flutter,” in

pressures in the airway resulting in loosening of mucus. Other PEP devices are used with a small volume nebulizer and function in conjunction with medication delivery. A recent Cochrane Review concluded that there was no clear evidence that PEP was a more or less effective intervention overall than other forms of physiotherapy, and there was limited evidence that PEP was preferred by participants compared with other techniques.[281] IPPB devices use pressure to passively fill the lungs when a breath is initiated. An incorporated manometer and mechanical valves serve to terminate the flow of inspired air when a predetermined pressure is reached on inhalation. IPPB breathing circuits are designed to nebulize inhaled medication. Most IPPB devices are powered by compressed air and are not suitable for home use. Mechanical percussors are typically electrical devices used in lieu of a caretaker's hands for chest percussion or vibration. Conventional chest physiotherapy is both labor intensive and time consuming. A high-frequency chest wall vibrating/oscillating device is currently available (The ABI Vest). Arens et al.[282] showed that in hospitalized patients with cystic fibrosis, high-frequency chest compression with the vest conventional chest physiotherapy was equally safe and effective when used during acute pulmonary exacerbations.

Humidification Systems

During spontaneous breathing, inspired air is warmed and almost completely humidified as it passes through the upper airways.[283] The use of an endotracheal or a tracheostomy tube bypasses the natural warming and humidifying functions of the upper airway. The mucosal surface below the artificial airway must then provide both humidification and heat to the inspired air. This may adversely affect mucociliary clearance.[283,284] If the inspired gases are not warmed to the body temperature, insensible water loss in the lung is increased. All gases used in respiratory therapy are dry with no moisture. Therefore these gases must have moisture added to them during delivery to the patients. When a gas is warmed, its relative humidity decreases.

Humidifiers can be classified into those that provide only humidity and those that provide both heat and humidity. There are several types of nonheated simple humidifiers. The simplest in design is the pass-over or blow-by humidifier. The second type is the bubble humidifier, probably the most common device used in respiratory therapy. In this device, the gas is directed below the surface of the water and allowed to bubble to the surface. A jet-humidifier produces an aerosol; humidity is provided by evaporation of the aerosol particles. An underwater jet humidifier uses a combination of jet and bubble humidification principles. In the clinical setting, the amount of humidity provided by the simple humidifiers is about the same. Although the more efficient humidifiers increase humidification, they also tend to cool the inspired air. Therefore the absolute humidity delivered tends to be similar among the simple humidifiers. Relative humidity of 100% at room temperature is less than 40% relative humidity at body temperature. When inspired gases are humidified with one of these devices, the balance of the moisture is provided by the airway mucosa. Therefore when the upper airway is bypassed by the presence of an artificial airway, then the inspired gases must be additionally heated to provide 100% humidity at body temperature. The factors that determine the efficiency of humidifying devices depend on (1) time of contact with the gas and water, (2)

temperature of both the gas and water, and (3) the surface area of contact of the gas-water interface. The efficiency of humidification increases as the time of contact increases and as the surface area of contact increases. Increasing the temperature of the inspired gas before delivery decreases the humidity that needs to be provided by the airway mucosa and adds to patient comfort. Heated humidifiers use the same principle as the simple humidifiers and have in addition a heating element. The relative humidity with these systems can be as high as 100%. The heating system can be servo-controlled to adjust the heat according to the relative humidity.

Aerosol Therapy

Aerosolized drug administration is often used in the treatment of infants and children with respiratory diseases including reversible lower airway obstruction, pneumonias due to *Pneumocystis carinii* and respiratory syncytial virus, and hyaline membrane disease. Common drugs used as aerosol agents include beta-2 agonists, atropine, ipratropium bromide, cromolyn sodium, antiviral agents, corticosteroids, antibiotics, surfactant, pentamidine, and mucolytics. A drug aerosol increases the therapeutic index of the drug by delivering it directly to the site of action with minimal side effects. The factors that affect deposition of aerosol particles are gravity, viscosity of the gas, kinetic activity of the particles, particle inertia, physical nature of the particle, temperature and humidity of the aerosol, and the ventilatory pattern. Compared with that in adults, deposition of aerosolized particles in infants and children is poor because of factors such as a small airway caliber, greater airway resistance, high respiratory rate with a short inspiratory time, increased chest wall compliance, ineffective coordination effort, and inconsistent breath-holding maneuvers. Despite poor aerosol deposition, a clinical response to inhaled medications can often be seen. The dose and the delivery method should be individualized to each patient to ensure a good clinical response.

Nebulizers are devices that generate aerosols. Particle size has to be at least 1 to 5 microns for deposition in the distal airways. Currently, four types of delivery systems are available for clinical use that generate medication aerosols. These are the jet nebulizers (small-volume and large-volume nebulizers), ultrasonic nebulizers, metered-dose inhalers, and dry-powder inhalers. A jet nebulizer uses the Bernoulli principle to create an aerosol. The size of the particle depends on the jet flow rate and size of the capillary tube. Baffles placed in the path of the aerosols tend to remove larger particles, allowing delivery of smaller particles to the patient. A pneumatic nebulizer is a device that creates the aerosol using the same principle as the jet nebulizer, but the aerosol particles are carried to the patient by a main gas flow. A pneumatic nebulizer may be a mainstream nebulizer in which the aerosol is generated in the path of the main gas flow or a sidestream nebulizer in which the aerosol is generated in a separate chamber and carried passively into the path of the main gas flow. The ultrasonic nebulizer uses a piezoelectric crystal that produces a highly concentrated output of aerosol particles and has been used primarily for cough and sputum production or bronchoprovocational challenges. Ultrasonic nebulizers have not been routinely used for drug delivery in infants and children. With the replacement of the saline solution with medication, however, the highly concentrated output from the ultrasonic nebulizer may perform better than a small-volume nebulizer in accomplishing greater deposition of medications in children.

The metered-dose inhaler uses a pressurized canister that dispenses a single bolus of aerosolized medication. Such inhalers are convenient, cost effective, and versatile, and generally have an effective deposition rate of 10% to 15%. The canister is activated into the spacer and the medication remains suspended in the chamber until the patient inhales. A dry-powder inhaler delivers a large bolus of medication during a single inspiration maneuver and produces therapeutic effects similar to a metered-dose inhaler and an aerosol nebulizer. The dry-powder medication, released from a capsule and deposited into a small canister, is delivered to the lungs during inspiration. The inspired flow rate causes a turbulent state within the canister, and the powder is directed toward the respiratory tract.

Aerosolized medications are often delivered through mechanical ventilators for the treatment of bronchospasm. Aerosol delivery is inefficient when delivered through a ventilator. The endotracheal tube is the most significant barrier to effective delivery. The smaller the inner diameter of the tube, the less efficient is aerosol delivery. The nebulizer is most effective when it is synchronized to fill the inspiratory limb of the circuit with aerosolized particles during the exhalation phase of ventilation, thereby improving the delivery of medication during the subsequent inspiration. The inspiratory portion of the circuit serves as a spacer chamber, similar to the spacer used for metered-dose inhalers. Some current ventilators offer a synchronized nebulization capability, in which a portion of the preset inspiratory gas is diverted to power the nebulizer. The effects of added volume delivered to the inspiratory limb should be taken into account and minimized with the addition of a pressure relief valve to the circuit. Metered-dose inhalers can be equally effective as nebulizers during mechanical ventilation.

Weaning From Mechanical Ventilation

Weaning from mechanical ventilation is defined as liberation from mechanical ventilation while spontaneous breathing is allowed to assume the responsibility for effective gas exchange. Weaning can be considered a success when a patient can maintain effective gas exchange, with complete spontaneous breathing and without any mechanical assistance. Weaning can be considered a failure when spontaneous efforts are incapable of sustaining effective gas exchange without mechanical ventilator support. Extubation is defined as the removal of an endotracheal tube. The timing of extubation should coincide with an assessment that the patient is capable of maintaining effective gas exchange without any mechanical ventilator support. Avoiding both premature extubation and unnecessary prolongation of mechanical ventilation is important.

When the indications that were met for provision of mechanical ventilation are no longer present, then the patient can be weaned from mechanical ventilation (Table 57.6). Weaning should start (1) when the underlying disease process is improving; (2) when gas exchange is adequate; (3) when no conditions exist that impose an undue burden on the respiratory muscles, such as cardiac insufficiency, severe hyperinflation, severe malnutrition, and multiple organ system failure; and (4) when the patient is capable of sustaining spontaneous ventilation as ventilator support is decreased without expending an excessive amount of energy. It is the patient who dictates the initiation of the weaning process and pace of the weaning process. Patients cannot be arbitrarily forced to wean. Improvement of the underlying disease

process can be assessed with measurement of indices of gas exchange, pulmonary mechanics, ventilation-perfusion relationships, and x-ray findings. The patient's ability to take over the responsibility from the ventilator depends on several factors: (1) respiratory muscle strength, (2) stability of the cardiovascular system, (3) work of breathing, (4) general nutritional status of the patient, and (5) the presence or absence of an underlying hypercatabolic state (eg, sepsis). Weaning cannot be accomplished unless all of these factors are optimal. The pathophysiologic determinants of weaning outcome include the following: (1) adequacy of pulmonary gas exchange; (2) respiratory drive; (3) respiratory muscle performance and capacity; (4) respiratory muscle load; (5) amount of dead-space ventilation; and (6) work of breathing and ventilatory requirements. Table 57.7 shows the specific parameters to be met before initiating weaning. There are currently two approaches to weaning. One is the "traditional" method of slowly reducing the ventilator support, including inspired oxygen concentration, to a minimal acceptable level and then assessing the patient's readiness to extubate. The other is the "modern" concept of assessing the patient's readiness to extubate as soon as the patient meets criteria to initiate weaning.

TABLE 57.6

Criteria to Be Met Before Initiating Weaning

1. Alert mental status
2. Good cough and gag reflexes
3. Core temperature below 38.5°C
4. Spontaneous respiratory effort
5. pH 7.32-7.47
6. Partial pressure of arterial oxygen (PaO_2) >60 mm Hg or pulse oximetry reading <95%
7. Fractional inspired oxygen (FiO_2) ≤0.50
8. Positive end-expiratory pressure (PEEP) ≤7 cm H_2O
9. Partial pressure of carbon dioxide ($PaCO_2$) <50 mm Hg
10. No further need for vasoactive agents
11. No clinical need for increased ventilator support in the past 24 hours
12. No planned operative procedures requiring heavy sedation in the next 12 hours

TABLE 57.7

Criteria for Terminating a Spontaneous Breathing Trial

1. Inability to maintain gas exchange Pulse oximeter saturations <95% with 40% inspired oxygen Needing >50% inspired oxygen to maintain oxygen saturations >95% 2. Inability to maintain effective ventilation Measured exhaled tidal volume <5 mL/kg An increase in $PaCO_2$ >50 mm Hg or an increase of >10 mm Hg Respiratory acidosis with pH <7.3 3. Increased work of breathing Respiratory rate outside of the acceptable range for their age for age	
<6 mo	20-60/min
6 mo-2 yr	15-45/min
2-5 yr	15-40/min
>5 yr	10-35/min
Use of accessory respiratory muscles Intercostals/suprasternal/supraclavicular retractions A paradoxical breathing pattern 4. Other signs of distress Diaphoresis Anxiety Heart rate higher than the 90th percentile for a given age	

Change in mental status (agitation or somnolence)
Systolic blood pressure lower than the third percentile for a given age

If a patient has any of these signs at any time during the breathing trial, the trial should be terminated and mechanical ventilation should be reinstituted.

$PaCO_2$, partial pressure of carbon dioxide.

Traditional Method of Weaning

In the traditional method, the exact sequence of the weaning process will be dictated by the clinical circumstance. At each step of weaning, the patient must demonstrate an ability to sustain effectiveness of breathing. Minute ventilation is reduced primarily with a decrease in the ventilator rate. Mean airway pressure is then reduced to a minimum with a decrease in CPAP/PEEP. Most children are currently weaned with SIMV or IMV alone, with SIMV and added pressure support, or with pressure support alone. Despite earlier indications that weaning with IMV was useful,[285,286] current studies do not advocate weaning with IMV in adults.[287,288] In infants, provision of a continuous flow device has been shown to decrease work of breathing and aid in weaning.[17] PSV has been advocated as a weaning mode because it can result in better synchrony between the patient and the ventilator than IMV, volume-assisted ventilation, or pressure-control ventilation.[289-292] Pressure support will allow ventilatory muscle loads to be returned gradually during the weaning process.[289-292] Because each breath is assisted, it alters the pressure-volume relationship of the respiratory muscles in such a way as to improve its efficiency.[289-292] The parameters that can be manipulated to titrate the muscle loading are the magnitude of the trigger threshold and the preset pressure limit. PEEP is provided to maintain FRC and prevent alveolar collapse. The amount of pressure support to be provided depends on the clinical circumstance. PSVmax, or the maximum pressure support needed to reduce the respiratory work to zero, requires a pressure limit that delivers a VTeff of about 10 to 12 mL/kg. PSVmax is not necessary at the start of weaning. The level of pressure support that should be selected should allow for spontaneous respiration without undue exertion and still result in normal minute ventilation. No strict criteria can be established; they have to be applied and titrated on an individual basis. Weaning of PSV is accomplished with a decremental reduction of the pressure limit. Similar to that previously mentioned in the weaning guidelines, with each wean, the effect of weaning on muscle loading has to be evaluated clinically. An increase in respiratory rate is an early indication of increasing muscle load. Retractions and use of accessory muscles would indicate a more severe muscle load. If respiratory rate increases during the weaning process, the level of pressure support should be increased until there is reduction in the respiratory rate. A relative contraindication to the use of PSV is a high baseline spontaneous respiratory rate. There is a finite lag time involved from the initiation of a breath to the sensing of this effort and from the sensing to the delivery of a mechanical breath. In infants breathing at a relatively fast rate (>50 breaths per minute), this lag time may be too long, and this may result in asynchrony between the patient and the ventilator.

"Modern" Method of Weaning

The premise underlying the modern method is that not all patients require a prolonged weaning process. Esteban et al.[287] showed that 76.2% of patients successfully underwent a 2-hour trial of spontaneous breathing, and 89.4% of them immediately underwent extubation. In a recently completed randomized, controlled trial of weaning modes in children, 42% of the patients initially tested with a minimal pressure-support trial passed the test and underwent extubation.[293] These studies validate the modern method of weaning patients from mechanical ventilation. If patients meet the criteria for weaning as outlined in Table 57.8, they can be subjected to a Readiness to Extubate Trial (RET) to test their ability to breathe spontaneously and maintain gas exchange. If the RET is successful, then the patient is ready to be extubated. If the patient fails an RET, there are two choices, either continuation of invasive mechanical ventilation or extubation to noninvasive ventilation. If invasive mechanical ventilation is continued, then the RET can be repeated in 24 hours. The level of invasive mechanical ventilator support should keep the patient comfortable with no increased work of breathing. If the decision is to extubate to noninvasive positive pressure support, then it would be prudent to test the patient on a level of pressure support that is necessary to maintain gas exchange and decrease the work of breathing. The criteria for terminating an RET are shown in Table 57.8.

TABLE 57.8

Threshold Values for Low- and High-Risk of Reintubation for Bedside Parameters of Respiratory Function

Respiratory Parameter	Low Risk (≤10%)	High Risk (≥25%)
Spontaneous tidal volume (mL/kg)	>6.5	<3.5
FIO_2	<0.3	>0.4
Mean airway pressure (cm H_2O)	<5	>8.5
Peak inspiratory pressure (cm H_2O)	<25	>30
Dynamic compliance (mL/kg/cm H_2O)	>0.9	<0.4
Fraction of the total minute ventilation provided by the ventilator (%)	<20	>30
Mean inspiratory flow (mL/kg/sec)	>14	<8

Respiratory parameters were measured just before extubation. Risk of reintubation is percent of patients who were reintubated within 48 h of extubation.

Readiness to Extubate Trial (RET)

Currently, there are three methods of RETs: (1) T-piece trials, (2) CPAP trials, and (3) minimal pressure-support trials.[287,288,293-296] In T-piece trials, the patient is removed from the ventilator but does not undergo extubation. Humidified supplemental oxygen is provided to the airway without any positive pressure support through a T-piece (Fig. 57.22).

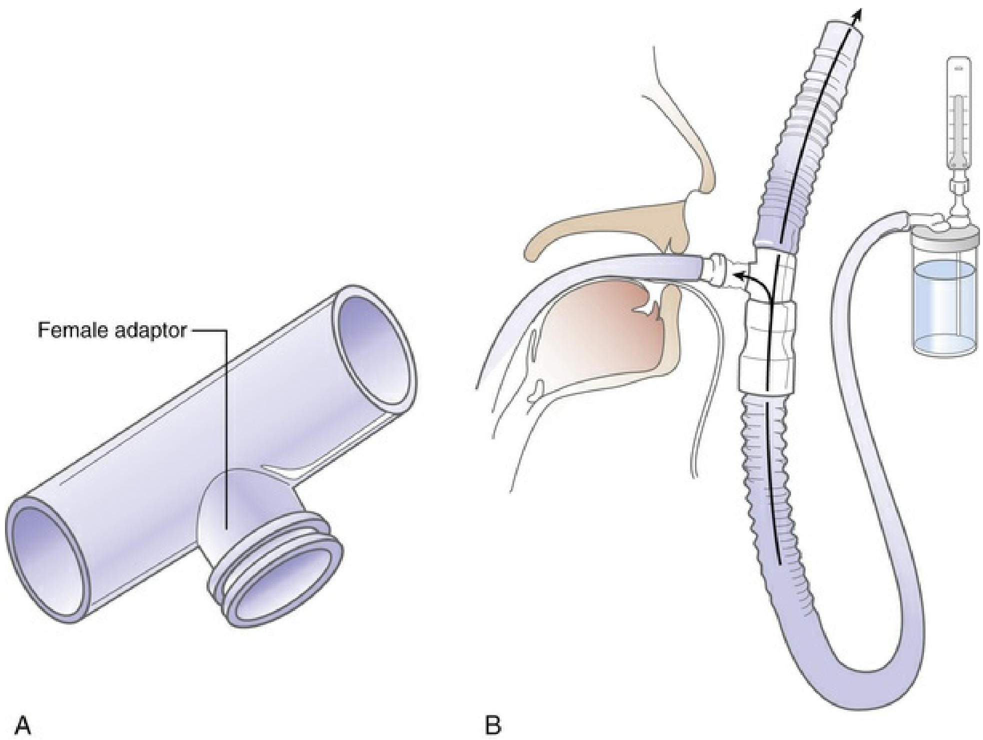

FIG. 57.22 (A and B) T-piece circuit. (Reproduced with permission from Kofke WA. Postoperative respiratory care techniques. Part III. Weaning from mechanical ventilation and oxygen therapy. Curr Rev RACN. 1992;13:161.)

In this system, a corrugated tubing from the nebulizer/humidifier attaches to one end of the T-piece, and an extension of corrugated tubing attaches to the other end of the T-piece. The flow rate should be adjusted to produce a constant mist coming from the extension piece on the T-tube during both inspiration and expiration so that the patient's minute ventilation is matched by the device. Roughly, this corresponds to at least about three times the minute ventilation of the patient.

The RET can also be conducted without removing the patient from the ventilator with a low level (eg, 5 cm H_2O) of CPAP or with a low level of PSV. Randolph et al.[293] described a minimal pressure-support technique in which the level of pressure support was adjusted for the endotracheal tube size (3–3.5 mm = pressure support of 10 cm H_2O; 4–4.5 mm = pressure support of 8 cm H_2O; >5 mm = pressure support of 6 cm H_2O). On the other hand, in a study comparing minimal pressure support with T-piece trials, Farias et al.[294-296] used a pressure support of 10 cm H_2O for all patients. The duration of the trial can range from 30 minutes to 2 hours. The proponents of a "minimal pressure-support" approach to the RET speculate that this overcomes the resistance to breathing through the artificial airway. Ishaaya et al.[297] showed that minimal pressure support based on in vitro studies overestimated the amount of support required to overcome the resistance of the endotracheal tube and ventilator circuitry. There are no measurements in vivo validating this concept in children. In one study of adults, the authors reported a similar resistance to breathing through the upper airway after extubation as that with the endotracheal tube in place.[298] Resistance through the artificial airway is affected by many factors, including the inspiratory flow of the patient, inner diameter of the tube, use of either an endotracheal or a tracheostomy tube, and presence of secretions in the tube. In

children, Farias et al.[295] recently compared two methods of RET, one with pressure support of 10 cm H_2O and the other with a T-piece circuit. The extubation failure was not different between the two groups.[295]

Physicians are reluctant to subject infants and young children to a trial of complete spontaneous breathing with either CPAP or a T-piece circuit because of concern about the work of breathing imposed by the endotracheal tube and the breathing circuit. Proponents of this paradigm routinely extubate patients after a "minimal pressure-support" RET. Willis et al.[299] showed elegantly that the work of breathing associated with T-piece breathing was similar to that with complete spontaneous breathing after extubation. In fact, this study showed that the work of breathing with all the support modes including minimal pressure support mode was considerably less than that after extubation. Taken together, these studies suggest that with support modes the patient is receiving a substantial amount of assisted ventilation. Therefore an RET performed with a support mode may not truly represent complete spontaneous breathing, and any evaluation made may overestimate the ability of children to breathe spontaneously when they are extubated. The studies by Farias et al.[294-296] have shown that RETs with a T-piece circuit are well tolerated by children. These should serve to dispel the myth that infants and children cannot be subjected to a T-piece trial before extubation. Despite these theoretic concerns, Farias et al.[295] showed that patients extubated using either T-piece or pressure-support trials had similar rates of reintubation. There is currently another school of thought that infants and children need not be subjected to an RET before extubation. Proponents of this practice routinely extubate infants and children from a "low" level of ventilator support. Studies in children, however, have shown that when the fraction of minute ventilation provided by the ventilator is more than 30%, the risk of extubation failure is increased.[300,301] It is preferable that the ability to breathe effectively be determined with complete spontaneous breathing without ventilator support. An important dictum to remember is that "the test for extubation readiness is not extubation."[302]

Extubation

When RET is successful, the patient can undergo extubation and be liberated from mechanical ventilation. The patient must be awake, be alert, and have airway protective reflexes. The patient must be breathing effectively, without undue exertion. Adequate gas exchange with a relatively low FiO_2 must be established. A stable cardiovascular system must be established. Metabolic, nutritional, and electrolyte balance must be ensured. Airway pressures must be reduced to a minimum. Extubation failure can be predicted using simple measures of respiratory function such as inspiratory drive, lung mechanics, gas exchange, and level of ventilator support before extubation.[300,301] A low risk is defined as an extubation failure rate of less than 10%, and a high risk of failure is defined as an extubation failure rate of at least 25%.[300,301] Table 57.9 lists the threshold values for the respiratory parameters with identified low- and high-risk values.[300,301] Additional parameters that may be useful in determining eligibility for extubation are an intrapulmonary shunt fraction less than 15% (requires pulmonary artery catheterization), a physiologic dead space less than 40%,[303] a vital capacity of at least 15 mL/kg, and a maximum negative inspiratory force of at least 30 cm H_2O.

TABLE 57.9

Factors to Be Considered in Children for Home Care

Patient selection
Medical assessment
Cardiopulmonary stability
Positive trend in weight gain and growth curve
Freedom from frequent respiratory tract infections
Characteristics of the family and child
Awareness
Motivation
Commitment
Home requirements
Safe electrical, plumbing, and heating systems
Telephone
Space
Health care support personnel
Nurses
Aides
Family and friends
Funding
Third-party
State
Other
Multidisciplinary home care team from the discharging institution
Physician specializing in technology-dependent patients
Nurse specializing in technology-dependent patients
Social worker
Respiratory therapist specializing in technology-dependent patients
Other services
Occupational therapy
Physical therapy
Speech therapy
Dietary services
Psychologist
Responsibilities of the home care team
Coordinator
Physician available on a 24-h basis
Referral to a local durable medical equipment company
Instruction of parents and caretakers
Assistance of family in securing funding
Family preparation
Training in cardiopulmonary resuscitation
Instruction in all aspects of home care plan
Instruction in use and maintenance of equipment
Psychologic impact
Techniques of instruction

Weaning Problems

Farias et al.[294-296] distinguish between two types of failure: trial failure and extubation failure. Trial failure is defined as a failure to sustain effective gas exchange and breathing during a trial of spontaneous breathing while the patient is still intubated. Extubation failure is defined as the requirement for reintubation within 48 hours after extubation. Some patients take longer than others to wean. Factors that prolong the weaning process are (1) slow resolution of the underlying disease process, (2) ventilatory pump failure, and (3) psychologic factors. In many instances, weaning is delayed because of the slow resolution of the underlying disease process. Ventilatory pump failure can be due to increased respiratory work load, decreased respiratory muscle capacity, or a combination of both. Decreased ventilatory drive may result from respiratory center dysfunction caused by sedative agents; neurologic disease, particularly if it affects the brain stem; sleep deprivation; and metabolic alkalosis.

Phrenic nerve injury usually results as a complication of birth trauma or operative procedures involving the heart and other thoracic structures.[304-306] This may result in either paresis or paralysis of one or both hemidiaphragms. When muscle weakness is present, weaning should generally be slow, allowing sufficient time for regaining muscle strength and endurance. Muscle training through an incremental increase in muscle work can be achieved by a gradual increase in the trigger threshold for assisted ventilation. Ventilatory requirements can be reduced with a decrease in carbon dioxide production with a reduction in excess caloric intake. Muscle loading may occur during IMV because of patient asynchrony. Asynchrony between the patient's breathing and the mechanical breaths may occur during both phases of the respiratory cycle. When the patient exhales while the ventilator delivers a mechanical breath, the airway pressures will be higher and the mechanical breath is wasted. This increases the work of breathing during exhalation. Prolonged asynchrony may result in muscle fatigue and may contribute to prolonged weaning. Considering nonrespiratory factors that may affect extubation failure is important. In a study by Khamiees et al.,[188] although all patients passed an RET, poor cough strength and endotracheal secretions were synergistic in predicting extubation failure. A recent article describes the current state of knowledge and evidence for many of the issues related to weaning and extubation.[307]

Tracheostomy and Weaning

Most airway resistance resides in the upper airways. Tracheostomy may aid in the weaning by several mechanisms. First, it reduces airway resistance by bypassing the upper airway. This reduces the work of breathing. Second, it increases patient comfort and allows better interaction between the patient and the caretakers, especially the parents. Third, it increases nursing comfort. Tracheostomy is not without risk. The procedure and complications of tracheostomy are described in detail elsewhere. Immediate complications are those related to bleeding, those related to pulmonary air leak, and those associated with anesthesia. Long-term complications include infections of the trachea and lung, granuloma formation with subglottic stenosis from scarring, erosion of the trachea, and bleeding from erosion into a major thoracic vessel (eg, innominate artery).

Home Respiratory Care

Chronic respiratory failure is defined as the requirement for mechanical ventilation for longer than a month. Due to improved medical care and technology, the prevalence of children surviving with chronic respiratory failure is increasing. In 1984, the Ad Hoc Task Force on Home Care of Critically Ill Infants stated that “the goal of a home care program for infants, children, or adolescents with chronic conditions is the provision of comprehensive, cost-effective health care within a nurturing home environment that maximizes the capabilities of the individual and minimizes the effects of disabilities.”[310] Respiratory care requirements in these children may range from supplemental oxygen to long-term mechanical ventilation. Long-term care in a tertiary care center is expensive and can alternatively be provided in a specialized chronic care rehabilitation center or at home. In 1986, the American College of Chest Physicians published guidelines for the management of

ventilator-dependent patients in the home and at alternate community sites.[311] Since the late 1970s and early 1980s, home care has been shown to be as safe as hospital care for infants with tracheostomies and infants and children requiring long-term mechanical ventilation.[312-318] The diagnoses included neuromuscular disease, spinal cord trauma, and respiratory failure from chronic cardiorespiratory disease.[172-178] Home care is psychosocially more acceptable to the families, is less expensive, and may provide a better quality of life for respiratory technology-dependent children.[319,320]

Indications for Home Respiratory Care

The goals of long-term home respiratory care include (1) provision of comprehensive, cost-effective respiratory care, (2) enhancement of quality of life, (3) reduction of morbidity, and (4) wherever possible, extend life. The major indication for home respiratory care is chronic respiratory failure. This may occur in children with parenchymal or airway disease or in children with normal lungs. In children with normal lungs, respiratory failure is usually due to central or peripheral nervous system dysfunction, neuromuscular disorders, or chest wall abnormalities. Patients who require home respiratory care generally fall under the following categories: (1) patients whose underlying disease is most likely to recover and therefore would need respiratory care during the recovery phase such as infants with bronchopulmonary dysplasia and children recovering from adult respiratory distress syndrome, (2) patients whose underlying disease is irreversible but not progressive such as patients with spinal cord injury, and (3) patients whose underlying disease is irreversible and progressive such as patients with muscular dystrophy. The approach to home care planning will be different depending on the natural course of the underlying disease.

Logistics of Home Care

Home care requires a team approach with interaction among several health care personnel—primary physician, home care nurses, respiratory therapists, social workers, sometimes the State Health Agency, and the family and patient (Table 57.9). First, the patient must be ready for home care.[318,320,321] In some patients, a stable tracheostomy with a mature stoma is essential. Inspired oxygen requirement should not be greater than 35%. PaO_2 should be greater than 60 to 70 torr with a $PaCO_2$ less than 60 torr with a normal arterial pH at relatively low ventilator settings. The family must demonstrate not only a desire to provide home care but also a minimal ability to provide various aspects of home care. Health care personnel must be available in the local community to assist the family in providing care. The home must have adequate facilities to maintain and run all necessary equipment and supplies. Contingency plans must be made for emergencies. The location of the home has major implications for home care. The home must be easily accessible by standard transportation. A home care provider should be available on a 24-hour basis to respond to emergencies. The home must have adequate space to accommodate all the caretakers and the required equipment. Discharge planning must be thorough and take into account all the factors listed in Table 57.9. A detailed description of the various respiratory care equipment used for home care is beyond

the scope of this chapter, and the reader is referred elsewhere.[322,323] A thorough knowledge of the limitations of various devices is essential for the respiratory care personnel coordinating home care. Parents who are motivated to providing home care for their children are willing to take on the cumbersome responsibility of carrying all the necessary equipment from place to place just to have the benefit of having the child at home.

CHAPTER 58

Noninvasive Ventilation

Concepts and Practice

Shekhar T. Venkataraman

PEARLS

- Not all patients are suitable for noninvasive ventilation. Careful selection is important for success.
- Noninvasive ventilation can be used for both short-term and long-term indications.
- Technologic advances in interfaces and equipment have allowed noninvasive ventilation to be used both at home and in the hospital.
- A team approach is crucial.
- Family involvement is essential for success.

Introduction

Conventional mechanical ventilation provided through endotracheal intubation or a tracheostomy is a lifesaving technique in the management of patients with respiratory failure. Endotracheal intubation and tracheostomy are associated with complications including injury to the airway and nosocomial infections. In addition, mechanical ventilation of children with endotracheal intubation often requires use of sedatives with its attendant side effects and complications. Positive pressure noninvasive ventilation (NIV) is provided by an interface that increases the proximal airway pressure, whereas negative pressure NIV is provided by creating a negative pressure around the chest wall. In both instances, the transpulmonary pressure is raised, causing airflow into the lungs. Continuous positive airway pressure (CPAP) refers to application of a constant pressure to the airway in which the patient's breathing efforts are unassisted. Continuous negative expiratory pressure (CNEP) refers to application of a constant negative pressure around the chest in which the patient's breathing efforts are unassisted. Spontaneous breaths may also be assisted using positive pressure delivered through the facial interface. Mechanical ventilation may be provided using negative pressure ventilation. Noninvasive ventilation can

be provided using either positive or negative pressure ventilators. This review describes the various noninvasive ventilatory techniques available, published reports on their efficacy, their advantages and disadvantages, and future directions. Throughout this chapter, NIV refers to assisted positive pressure noninvasive ventilation, CPAP is referred to separately, and negative pressure ventilation is described at the end of the chapter.

Historical Perspective

The first tank respirator was described in 1832 by John Dalziel of Scotland.[1] He designed an airtight box in which the patient was placed in a sitting position with the head and neck outside. Negative pressure was created inside the box using a system of bellows, a piston rod, and a one-way valve.[1] Dalziel, in 1832, reported the use of a bellows-operated box with a seal around the neck or shoulders to provide artificial respiration to a drowned seaman.[1] The first workable, manually operated, noninvasive negative pressure ventilator was designed by Woillez in 1867.[2] Doe, in 1889, described a box used for resuscitating newborns.[3] Since then there have been many designs of tank respirators in the late 19th and early 20th century. A detailed description is beyond the scope of this chapter, and the reader is referred to excellent reviews on this topic by Woollam.[4,5]

Drinker developed the first tank ventilator in 1928, but the first demonstration of prolonged use of this tank respirator was published in 1929 by Drinker and McKhann.[6]

Artificial respiration was maintained almost continuously for 122 hours in a girl, aged 8 years, suffering from acute anterior poliomyelitis, without discomfort or apparent harm to the patient. Administration of artificial respiration did not prohibit sleeping or the taking of nourishment. Though the patient died of pneumonia and cardiac failure, this report showed the feasibility of prolonged mechanical ventilation with a tank respirator. The description of the apparatus for use in adults, children, and infants was subsequently published in 1929.[7,8] The Drinker tank ventilator was subsequently used with great clinical value in patients with poliomyelitis.[9-15]

Negative pressure ventilation was introduced for use with neonates in the 1960s.[16,17] In 1953, Lassen reported that positive pressure ventilation administered using an endotracheal tube or a tracheostomy was more successful that negative pressure ventilation in treating patients with poliomyelitis.[18] Major technologic advances in the design of positive pressure ventilators led to the marked decrease in negative pressure ventilation. Noninvasive positive pressure ventilation by face mask was first employed by Barach et al.[19] for the treatment of hypoxemic respiratory failure secondary to acute pulmonary edema. Gregory et al.,[20] in 1971, reported that CPAP through nasal prongs was effective in improving oxygenation in neonates with hyaline membrane disease. Vidyasagar and Chernick[21] showed that constant negative pressure applied about the chest and abdomen was as effective as CPAP in improving oxygenation in neonates with hyaline membrane disease. Despite these early reports, noninvasive ventilation did not become popular until more recently. Ellis et al.[22] were the first to report the successful use of NIV through a nasal mask on a 6-year-old with severe alveolar hypoventilation. There is currently a renewed interest in noninvasive ventilation coinciding with technologic advances

in the manufacture and design of noninvasive ventilators. NIV through a mask for neuromuscular disorders was pioneered in the 1980s by Rideau et al.[23] and subsequently by Bach et al.[24]

Indications

The indications for the use of NIV can be categorized into short-term and long-term NIV. Short-term NIV is indicated where positive pressure support is needed acutely in a hospital setting in acute care or critical care areas for conditions that are reversible within a few days. Long-term NIV is indicated in conditions where respiratory failure is likely to be chronic or progressive.

Short-Term Noninvasive Ventilation

The indications for use of NIV in acute care and critical care situations are given in Table 58.1. The selection guidelines are given in Table 58.2. Four questions must be answered before attempting short-term NIV. They are as follows:

1. Does the patient have an irreversible cause of respiratory failure?

2. Can the patient's gas exchange be maintained without positive pressure?

3. Does the patient require immediate intubation and invasive mechanical ventilation?

4. Does the patient have any contraindications to the use of NIV (see Table 58.2)?

TABLE 58.1

Indications for Short-Term Noninvasive Ventilation

Acute Hypoxemic Respiratory Failure
Acute lung injury
Acute cardiogenic pulmonary edema
Pneumonia
Acute Lower Airway Disease
Acute asthma
Avoiding Intubation
Immunocompromised patients
Restrictive chest diseases
Neuromuscular disorders
Postoperative respiratory failure
Do not intubate patients
Postextubation respiratory failure
Facilitate Weaning and Extubation

TABLE 58.2

Selection Guidelines for Short-Term Noninvasive Ventilation

A. Potentially reversible condition
B. Need for ventilatory assistance
Moderate to severe increase in work of breathing
Tachypnea
Retractions
Paradoxical breathing
Accessory muscle use
Gas exchange criteria
Ventilatory failure ($PaCO_2$ >45 mm Hg with a pH <7.35)
Oxygenation failure (PaO_2/FiO_2 ratio <200)
C. Contraindications to noninvasive ventilation
Respiratory or cardiac arrest
Unstable (hypotension, shock)
Poor airway protective reflexes
Recent upper airway and esophageal surgery
Excessive secretions
Uncooperative
Agitation
Untreated pneumothorax
Inability for a good mask fit
Rapidly progressive neuromuscular weakness (eg, Guillain-Barré syndrome)

If the answer to any of these question is in the affirmative, then the patient may not be a suitable candidate for short-term NIV. If the answers to all these questions are in the negative, then the patient can be considered a candidate for NIV. Additional questions that the clinician needs to consider are the following:

1. Does the patient only need increased positive airway pressure to recruit the lung to improve oxygenation? If the patient needs only increased airway pressure to recruit atelectatic lung and to maintain lung volumes, then the patient can be placed on noninvasive CPAP through an appropriate interface.

2. Does the patient need additional ventilatory assistance on the basis of clinical signs and symptoms or gas exchange derangements? If the patient needs ventilatory assistance, the patient is a candidate for NIV.

Fig. 58.1 shows the algorithm to be followed for initiation and weaning of NIV in acute respiratory failure. If NIV is used in acute situations, there should be a determination every hour for up to 2 to 3 hours whether the patient has improved (see Fig. 58.1). Signs of success and failure are given in Table 58.3. A good response to NIV is indicated by (1) decreased respiratory rate, (2) reduced work of breathing, (3) improvement of dyspnea, (4) an increase in pH, (5) better oxygenation, and (6) decreased arterial carbon dioxide ($PaCO_2$) levels. Additionally, there may be hemodynamic effects such as a reduction in heart rate, improved blood pressures, and perfusion. Generally, for short-term use, NIV is used continuously until the patient improves or fails NIV. The goals of short-term NIV are given in Table 58.4.

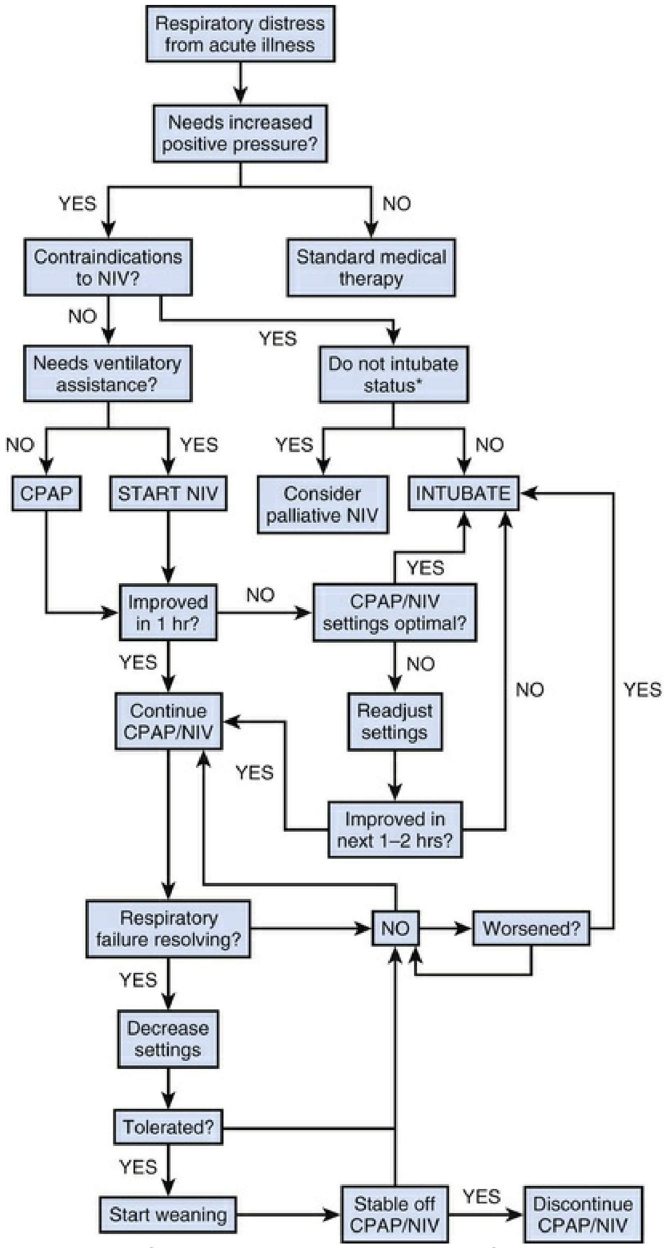

FIG. 58.1 Algorithm for initiation and weaning of short-term continuous positive airway pressure and noninvasive ventilation.

TABLE 58.3

Signs of Success and Failure Within 1 to 2 Hours of Application of Noninvasive Ventilation (NIV) for Short-Term NIV

Signs of success
Reduction in respiratory rate to a range that is normal for age
Absence of retractions
Absence of paradoxical breathing
Improvement in gas exchange
Improved pH
Improved PaO_2/FiO_2
Reduction in $PaCO_2$
Signs of failure
No change in signs of work of breathing
No change in gas exchange

Hemodynamic instability
Signs of respiratory fatigue
Change in mental status
Increased agitation

TABLE 58.4
Goals of Noninvasive Ventilation (NIV)

Short-Term NIV
Relieve respiratory distress
Decrease work of breathing
Improve gas exchange
Avoid intubation
Long-Term NIV
Ameliorate symptoms
Improve gas exchange
Improve quality of life
Improve sleep duration and quality
Improve survival

Adult Studies on the Short-Term Use of Noninvasive Ventilation

Acute Cardiogenic Pulmonary Edema

CPAP was described by Barach et al.[19] for the treatment of acute cardiogenic pulmonary edema. Several studies, including multiple randomized trials, have shown that the use of CPAP or NIV improves outcomes in cardiogenic pulmonary edema.[25-34] These studies show that the use of CPAP/NIV has the following favorable effects: (1) a rapid reduction in respiratory rate, dyspnea, and work of breathing; (2) a reduced rate of endotracheal intubation; and (3) a trend toward reduced mortality.[25-34] Physiologic mechanisms underlying the improvement are likely due to an increase in functional residual capacity, increased lung compliance, reduced work of breathing, and an improved cardiac performance due to reduced preload and afterload.

Acute Respiratory Failure/Acute Respiratory Distress Syndrome/Pneumonia

Adult studies have shown that NIV can be used in hypoxemic respiratory failure with an arterial oxygen tension to fraction of inspired oxygen (PaO_2/FiO_2 ratio) of less than 300, with bilateral parenchymal disease to prevent endotracheal intubation. Ferrer et al.[35] showed that NIV reduced the intubation rate from 52% to 25% with a reduction in ICU mortality from 39% to 18%. But this finding must be tempered with studies that show that NIV may not reduce the need for endotracheal intubation.[36,37]

A recent systematic review showed that NIV for acute hypoxemic respiratory failure was associated with a significantly lower rate of endotracheal intubation than standard management with a risk reduction of about 25%.[37] Overall, there was a reduction in hospital mortality of about 10% to 17%.[38]

Chronic Obstructive Pulmonary Disease

In adults with acute exacerbations of chronic obstructive pulmonary disease (COPD), NIV has improved both short-term and long-term outcomes.[39-45] Compared with standard therapy, NIV decreased the need for endotracheal intubation, reduced hospital mortality, and reduced the length of stay in the hospital, especially for those who had hypercapnia with respiratory acidosis.[46-51] A recent review strongly recommended the use of NIV for an acute exacerbation of COPD.[46] It is reasonable to expect a similar response to acute asthma since many of the pathophysiologic features are similar. Uncontrolled studies showed improvement in patients with an acute asthmatic attack.[47,48] Three small RCTs have been published on using NIV with acute exacerbation of asthma.[49-51] Holley et al.[49] did not find any difference in outcomes with the use of NIV. Sorosky et al.[50] showed that there was a rapid improvement measure of lower airway obstruction and fewer patients were admitted to the hospital.[50] In a recent three-arm trial, there was a greater reduction in dyspnea and a greater increase in the forced expiratory volume in the first second with NIV.[51]

Immunocompromised and Oncology Patients

It is desirable to reduce the probability of nosocomial infections in immunocompromised patients. Therefore it is appealing to apply NIV to avoid endotracheal intubation in these patients. Adult studies have shown that NIV can reduce the rate of endotracheal intubation, make possible earlier hospital discharge, and reduce the incidence of serious complications.[52-55] Despite aggressive management, some end-stage oncology patients experience breathlessness and dyspnea due to respiratory failure. NIV may alleviate the symptoms and provide comfort.[56-58] Nava et al. showed that application of NIV to these patients reduced their breathlessness and reduced the total dose of morphine administration to suppress dyspnea.[59]

Perioperative Respiratory Failure

Adult studies have shown that respiratory insufficiency that develops postoperatively in patients can be successfully treated with NIV. NIV reduces the rate of intubation and is more effective than CPAP or chest physiotherapy.[60,61] In patients after lung resection surgery, NIV reduced the rate of intubation and mortality compared with conventional therapy.[62] Adults with restrictive chest diseases who develop respiratory failure after surgery such as spinal fusion are also good candidates for NIV if they develop postoperative respiratory failure provided they do not have any other contraindications.

Facilitation of Weaning and Extubation

Endotracheal intubation and invasive mechanical ventilation are associated with complications including ventilator-associated pneumonia, ventilator-induced lung injury, and airway trauma. To minimize these complications, it is desirable to extubate the patient as quickly as possible. Generally, extubation coincides with the end of weaning (ie, the patient is not placed on any form of positive pressure support post extubation). In patients who take a long time to wean but require fairly low ventilatory assistance, it is possible to extubate them to NIV. Theoretically, it would reduce the incidence of complications associated with endotracheal intubation and invasive mechanical ventilation. Udwadia et al.[63] were one of the first to test this paradigm in 22 adult patients who were successfully stabilized on NIV following extubation. Recent adult studies have demonstrated that the use of NIV resulted in a reduction in the duration of mechanical ventilation, a reduction in the incidence of nosocomial pneumonia, and a reduction in the duration of hospital stay.[64-67]

Weaning and Postextubation Failure

NIV has been successfully used in weaning patients who had acute-on-chronic respiratory failure.[68] Recently, some adult studies have examined the use of NIV for postextubation respiratory failure (ie, respiratory failure that develops after extubation on complete spontaneous breathing).[69,70] The rationale for the use of NIV in this circumstance is the avoidance of endotracheal intubation. In at least one study in the adults, this approach was shown to increase the time from respiratory failure to intubation with an increase in mortality rate.[69,70]

Pediatric and Neonatal Studies

In 1993, Akingbola et al.[71] published a case report describing effective NPPV therapy in two pediatric-age patients with acute respiratory distress. Padman et al.[72] published a preliminary report on 15 patients aged 4 to 21 years who had respiratory failure due to cystic fibrosis (4 patients) and neuromuscular disease (11 patients). In 14 patients, the placement of an artificial airway was avoided. They observed significant improvement in hospital days, respiratory rate, heart rate, serum bicarbonate, arterial carbon dioxide, dyspnea, activity tolerance, and quality of sleep. Since that time, NIV has been applied to pediatric patients with a variety of respiratory disorders. There has been a significant increase in the number of articles since 2004 showing the growing interest and expertise in the use of NIV in children.[73] The following is a summary of the studies of acute short-term NIV in infants and children.

Acute Short-Term Indications

Acute Respiratory Failure

Just as in adults, NIV has been used successfully in infants and children with acute respiratory failure due to parenchymal lung disease, acute respiratory distress syndrome (ARDS), bronchiolitis, pneumonia, and other lung infections.[74-76] In 1995, Fortenberry et al. reported a retrospective study on the efficacy and complications of

NIV in 28 children with acute hypoxemic respiratory insufficiency.[76] NIV significantly decreased respiratory rate and improved both oxygenation and ventilation. The use of NIV decreased hospitalization rate and increased patient comfort. Only 3 of 28 patients required intubation or reintubation.[76] Padman et al.[77] conducted a prospective study in 34 patients with impending failure, all of whom required airway or oxygenation/ventilation support and required admission to the pediatric ICU. A decrease in respiratory rate, heart rate, and dyspnea score, as well as an improvement in oxygenation, was noted in more than 90% of patients studied. The frequency of intubation in these patients was only 8%.[77] In a study by Essouri et al.,[78] a total of 114 patients were treated with NIV, among whom 83 (77%) were successfully treated without intubation. NIV failure was associated with more severe illness and a diagnosis of ARDS.[78] Joshi and Tobias[79] reported on a 5-year experience with primary respiratory failure and postoperative respiratory failure. Application of NIV improved gas exchange, decreased inspired oxygen requirement, and decreased respiratory rate in 29 patients with primary respiratory failure.[79] Munoz-Benet et al.[80] reported on a 3-year prospective noncontrolled study in 26 children with acute respiratory failure (ARF). Pneumonia was observed in most of the children (46.8%). There was a significant improvement in the respiratory rate, heart rate, pH, carbon dioxide levels, and oxygen saturation at 2 to 4 hours, which was sustained for 24 hours. Only four patients required intubation. All patients survived.[80]

Cambonie et al.[81] were the first to demonstrate the efficacy of nasal CPAP in young infants with respiratory failure secondary to acute respiratory syncytial virus bronchiolitis. Nasal CPAP improved respiratory symptoms and signs as measured by a clinical score.[81] Inspiratory time to total time ratio decreased, and work of breathing assessed by esophageal manometry also decreased significantly.[81] The mechanism of improvement with CPAP is unloading of respiratory muscles.[81] Javouhey et al.[82] reported their experience using NIV as a primary means of support in infants with respiratory failure secondary to acute bronchiolitis. In the year before using NIV, there were 53 patients and 27 patients in the year when NIV was used as a primary mode of respiratory support.[82] Eighty-nine patients were intubated in the year before NIV was applied, but only 52% were intubated during the NIV period. Fewer patients required supplemental oxygen (10/27) for more than 8 days compared with 33/53 patients in the previous year.[82] NIV also reduced the incidence of ventilator-associated pneumonia.[82] Several moderately large retrospective studies have shown that CPAP or NIV decreased work of breathing, respiratory symptoms, and signs; improved gas exchange; and reduced the need for intubation.[83-86]

In 2008, Yanez et al.[87] reported on a prospective, randomized, controlled trial of NIV in children with acute respiratory failure. Compared with control patients, children treated with NIV had improvement in heart rate, respiratory rate, and gas exchange.[87] The NIV group had a significantly lower rate of endotracheal intubation than control patients (28% vs. 60%, respectively).[87] There have been two RCTs using CPAP with bronchiolitis.[88,89] Thia et al.,[88] in 2008, showed that infants with bronchiolitis randomized to receive CPAP for hypercarbia had improvement in capillary PCO_2 while the control infants had a slight increase in capillary PCO_2.[88] Chidini et al.[89] compared CPAP delivered by helmet or facial mask in infants with acute respiratory failure secondary to bronchiolitis due to respiratory syncytial virus.[89] CPAP by helmet had a lower rate of intolerance (17% vs. 54%) while the

intubation rates were similar. In patients who tolerated CPAP, gas exchange and breathing pattern improved with both interfaces.[89] CPAP by mask had a greater incidence of cutaneous sores and leaks.[89]

Status Asthmaticus

Initial reports of the use of NIV with status asthmaticus were mainly case reports.[72,76,77] In one of the first reports of the use of NIV in children by Fortenberry et al.,[76] there were two patients with status asthmaticus. In the case series reported by Padman et al.,[77] there were two patients with reactive airway disease. Teague et al.[90] reported that NIV treatment acutely improved oxygenation and reduced cardiorespiratory distress in 19 out of 26 patients with status asthmaticus. This group of “NIV responders” had significantly shorter lengths of stay in both the ICU and hospital. However, the seven nonresponders required endotracheal intubation as respiratory distress progressed despite sedation. Akinbola et al.[91] reported the use of NIV in three children with status asthmaticus and showed an improvement in ventilatory parameters. Thill et al.,[92] in a randomized, crossover study in children with lower airway obstruction, showed that NIV decreased signs of work of breathing such as respiratory rate, accessory muscle use, and dyspnea as compared with standard therapy with no serious associated morbidity. Carroll et al.[93] reported the use of NIV in five children, four of whom were obese. Needleman et al.[94] was the first to demonstrate that application of NIV improved work of breathing, phase angles, and other respiratory parameters, and discontinuation of NIV was associated with worsening of the respiratory signs. Since then, there have been several large series on the use of NIV in status asthmatics.[95,96] In 2007, Beers et al.[95] reported a retrospective study on the application of NIV in 83 children with status asthmaticus. There was an immediate improvement in symptoms in almost 80% of the patients.[95] Almost 90% of the patients tolerated NIV, and of those 22% did not require admission to the PICU.[95] In 2011, Mayordomo-Colunga et al.[96] prospectively enrolled 72 patients with status asthmaticus. Sixty-seven responded to NIV with improvement in clinical scores, respiratory rate, heart rate, and blood gas parameters.[96] Response was seen within an hour of placement of NIV and was sustained.[96] Only five patients failed and required intubation.[96]

Cardiac Patients

Chin et al.[97] reported on the successful use of NIV after congenital cardiac surgery in two infants younger than 1 year of age. Gupta et al.[98] reported a large, retrospective study on the use of NIV after cardiac surgery. NIV was used as either a “prophylactic” approach (58 events), where NIV was applied on extubation from invasive mechanical ventilation, or a “nonprophylactic” approach (163 events), where NIV was applied after extubation only when there were signs and symptoms of respiratory failure.[98] CPAP was used in 201 events with a success rate of 78%, and NIV was used in 20 events with 80% success rate.[98] Factors associated with response to NIV were a lower risk-adjusted classification for congenital heart surgery, presence of atelectasis, steroid therapy received within 24 hours after NIV, and normal heart rate and oxygen saturations demonstrated within 24 hours after initiation of NIV.[98] A similar but prospective study was reported by Kovacikova et

al.[99] over a 3-year period. There were 107 episodes of NIV use in 82 patients. In almost 60% of the patients, NIV was used successfully without the need for tracheal intubation.[99]

Immunocompromised and Oncology Patients

Although oncology patients have been included in previous reports on the use of NIV in acute respiratory failure, Otonello et al.[100] were the first to report on the use of NIV of only oncology patients. Twenty patients with either hypoxemic or hypercapnic respiratory failure were treated with NIV. Fifteen out of 20 patients showed marked improvement in oxygenation and ventilation.[100] Pancera et al.[101] reported an 8-year experience of using NIV in children with oncologic disorders. NIV as the first-line therapy was compared with invasive mechanical ventilation.[101] This study included 120 patients who were treated with NIV and 119 who were intubated and mechanically ventilated as the first-line therapy.[101] The overall success rate of NIV was 74.2%. Seventy-five percent of the patients treated with NIV did not require endotracheal intubation, showing that NIV is a viable first-line therapy for respiratory failure in immunocompromised patients for preventing endotracheal intubation.[101] Cardiovascular dysfunction, severe illness score, and solid tumors were predictive of NIV failure in these patients. Piastra et al.[102] enrolled 23 consecutive immunocompromised children with ARDS who were treated with NIV using a helmet or face mask. For all the patients, NIV response rates were 82% and 74%, for early and sustained improvement, respectively.[102] NIV was successful in improving gas exchange and respiratory distress when there were both early and sustained responses.[102] Severe sepsis and septic shock were associated with NIV failure. All patients who were successfully managed by NIV survived.[102]

Other Indications

There are several small reports of the use of NIV for postextubation respiratory failure.[77,79,103-105] More recently, NIV has been suggested as an alternative to endotracheal intubation for the perioperative management of scoliosis correction in patients with muscular dystrophy.[106] NIV has also been used in children after liver transplantation to facilitate extubation and prevent reintubation.[107,108]

NIV has been used successfully to improve symptoms of obstructive sleep apnea.[109-112] Teague et al.[109] showed that NIV improves gas exchange in children with upper airway obstruction. Rosen et al.[110] also showed that CPAP and NIV were used successfully to manage the preoperative and/or postoperative upper airway obstruction in children with obstructive sleep apnea. Friedman et al.[111] reported using NIV on nine patients after adenotonsillectomy to treat postoperative obstructive symptoms. They showed that NIV is effective after adenotonsillectomy to avoid the risks of intubation and ventilator dependence.[111] Essouri et al.[112] published a prospective, randomized, controlled study comparing standard therapy with CPAP and NIV in upper airway obstruction in the postoperative period. During spontaneous breathing, patients were tachypneic with a high inspiratory time (Ti) to total respiratory time (Ttot) (Ti/Ttot). Esophageal pressure measurements and swings were elevated, reflecting an increased work of breathing, but could not maintain normal gas exchange.[112] Both CPAP and NIV resulted in a significant

decrease in all indices of respiratory effort.[112] During NIV, there were significantly high ineffective inspiratory efforts due to ineffective or delayed triggering.[112]

Long-Term Noninvasive Ventilation

Long-term NIV is indicated in conditions that result in chronic respiratory failure. This can be either progressive or nonprogressive. Generally, long-term NIV is intermittent with periods of time off NIV. The most common form of long-term NIV is nocturnal NIV with off-periods during the daytime. The goals of long-term NIV are given in Table 58.4. The indications for long-term NIV are given in Table 58.5.

TABLE 58.5

Indications for Long-Term Noninvasive Ventilation

Restrictive thoracic diseases
Chest wall deformity—kyphoscoliosis
Slowly progressive neurologic disorders
Postpolio syndrome
Muscular dystrophies
Spinal muscular atrophy
Nonprogressive chronic respiratory failure
High spinal cord injury
Chronic lung disease
Cystic fibrosis

Physiologic Effects and Outcomes of Long-Term Noninvasive Ventilation

Neuromuscular Disorders

Patients with neuromuscular and chest wall disorders often have sleep-related disturbances.[113] In adults, intermittent NIV consistently improves daytime gas exchange.[114,115] NIV ameliorates hypoventilation, intermittent sleep apneas, and other sleep-disordered breathing.[116] NIV, applied appropriately, improves the quality of life with restrictive thoracic disorders.[117]

In the 1970s and 1980s, intermittent positive pressure ventilation through a mouthpiece was used to treat respiratory failure late after poliomyelitis or Duchenne muscular dystrophy.[118-120] In 1993, Bach et al.[121] published the results of application of a clinical protocol to manage patients with Duchenne muscular dystrophy. The protocol consisted of using NIV and assisted coughing (both manually and mechanically operated) to maintain normal oxygen saturation monitored by a pulse oximeter, particularly during intercurrent upper respiratory tract infections.[121] They showed that strict adherence to the protocol was associated with decreased hospitalization and increased survival.[121,122] These studies show that noninvasive respiratory aids can prolong survival and permit extubation or decannulation of patients with Duchenne muscular dystrophy with no breathing tolerance.[121,122] Mellies et al.[123] showed that long-term noninvasive ventilation in children and adolescents with neuromuscular disorders (non-Duchenne muscular dystrophy) improved both nocturnal and diurnal gas exchange and sleep.

Initial reports on the use of NIV in children with infantile SMA showed that it was

feasible, but survival was not prolonged.[124] In 2002, Bach et al.[125] reported comparing the outcomes of patients with SMA type 1 who developed respiratory failure before age 2 years and either had tracheostomy tubes or used NIV-assisted coughing. Tracheotomized patients were hospitalized less frequently until they were 3 years of age but had more after 5 years of age when compared with the patients who were treated with NIV and assisted coughing.[125] With respiratory support as outlined earlier, both groups survived between 8 and 12 years on average.[125] The use of NIV along with assisted coughing has increased survival in children with SMA type 1.[126-130] In children with neuromuscular disorder, symptoms of daytime sleepiness, headache, and sleep quality improve after initiation of NIV.[129] Hospitalization rates and health care costs decreased. Quality of life remained stable after NIV, despite disease progression.[129] Children with spinal muscular atrophy (types 1 and 2) often develop thoracoabdominal asynchrony, especially during sleep. NIV improved sleep breathing parameters and thoracoabdominal coordination during sleep in SMA types 1 and 2.[130]

Cystic Fibrosis

The role of NIV in patients with cystic fibrosis is emerging. Initially, NIV was used in end-stage lung disease as a bridge to transplantation.[72,131-133] These studies suggest that the waiting time can be extended while keeping the patient comfortable.[72,131-133] It is also being used to treat acute or chronic respiratory failure and sleep disturbance.[134-139]

In 1981, Sullivan et al.[140] first demonstrated that nasal CPAP was effective in reversing obstructive sleep apnea in four adults and one teenager. Guilleminault et al.,[141] in 1986, reported that nasal CPAP reversed or reduced obstructive sleep apnea in some children while there were problems related to poor cooperation from parents and difficulty in preventing leaks around the nasal mask. Since the first report, several studies have shown that nasal CPAP was effective in obstructive sleep apnea in infants and children.[142-146] In 1995, Guilleminault et al.[147] reported that nasal CPAP was successful in 70 out of 72 infants with sleep-disordered breathing. In many instances, it provided an interim solution while allowing the patient to grow and postponing surgery.

Interfaces

A properly fitting facial appliance is essential for the optimal application of NIV. There are currently several devices in use: (1) Adam's Circuit and nasal pillows, (2) nasal masks, (3) oral-nasal masks, (4) total face masks, and (5) helmet or head hood and six mouthpieces. A correctly sized interface minimizes leaks, improves effectiveness of positive pressure support, and improves comfort.

Adam's Circuit: This device uses a "nasal pillow," which attaches to a manifold that is placed over the top of the head (Fig. 58.2). Some patients prefer this to the nasal mask. "Nasal pillows" are available in various sizes (see Fig. 58.2).

FIG. 58.2 Adam's Circuit and nasal pillows. Adam's Circuit (A), ResMed SwiftTM FX Bella (B), Medical Innovations PediFlow (C), Fisher and Paykal Pilairo Q (D), and Innomed Technologies Nasalaire II Petite (E). (Courtesy manufacturers.)

Nasal masks: A nasal mask rests between the bridge of the nose and above the upper lip (Fig. 58.3). As a rule, the smaller the mask, the better the fit. In patients who are unable to keep their mouth closed, chin straps may be used to close the mouth.

FIG. 58.3 Nasal masks. Respironics PN831 (A), Respironics PerformaTrak (B), Respironics Contour Deluxe (C), ResMed Mirage (D), Airon Nasal Masks (E), and Fisher and Paykal HC407 (F). (Courtesy manufacturers.)

Oral-nasal masks: This is the most common interface used to provide NIV (Fig. 58.4). The ideal face mask should (1) be made of a clear material to allow visual inspection, (2) conform to the contours of the patient's face, (3) be easily moldable from its factory shape, (4) be soft and not apply excess pressure on the skin of the face, and (5) maintain its deformed shape (has "memory") when it is removed. The mask should extend from the bridge of the nose to just below the lower lip. The mask is secured using an anchoring system that goes around the head.

FIG. 58.4 Oronasal masks. Respironics AF531 (A), Respironics AF811 (B), Respironics AF421 (C), Fisher and Paykal HC431 (D), ResMed Ultra Mirage (E), and ResMed Quattro FX (F). (Courtesy manufacturers.)

Total face mask: This mask covers the whole face including the eyes (Fig. 58.5). The advantage of a total face mask is that it does not have to conform to the shape of the face and therefore does not have to be molded to fit every patient. The disadvantage is that it has an increased deadspace, and therefore there may be difficulty in eliminating CO_2.

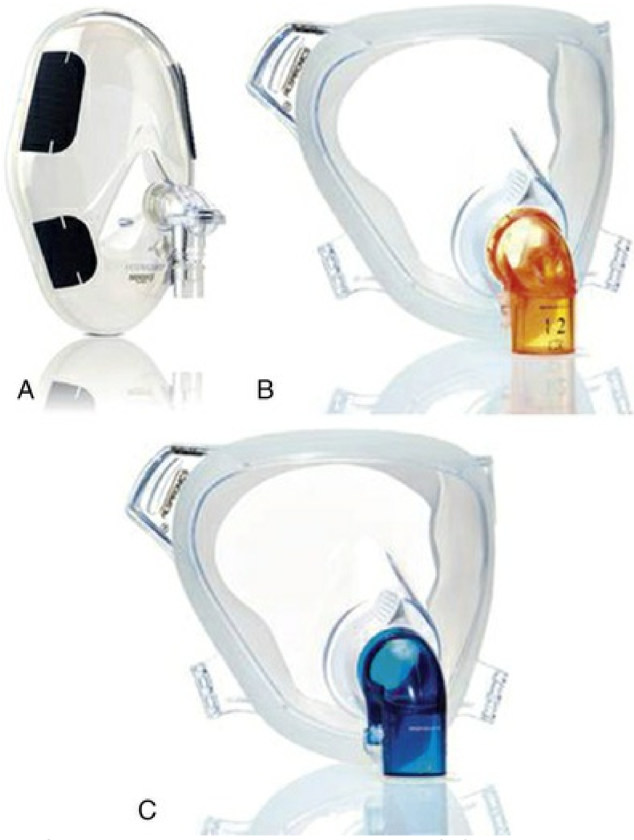

FIG. 58.5 Full-face masks. Respironics Total (A), Respironics PerforMax Single Use (B), Respironics PerforMax Multi-Use (C).

Head hood: Also called a "helmet," it has been used successfully in a number of European ICUs (Fig. 58.6). It appears best suited for application of CPAP. Dead space is a major concern and therefore should be reserved for patients in the ICU.

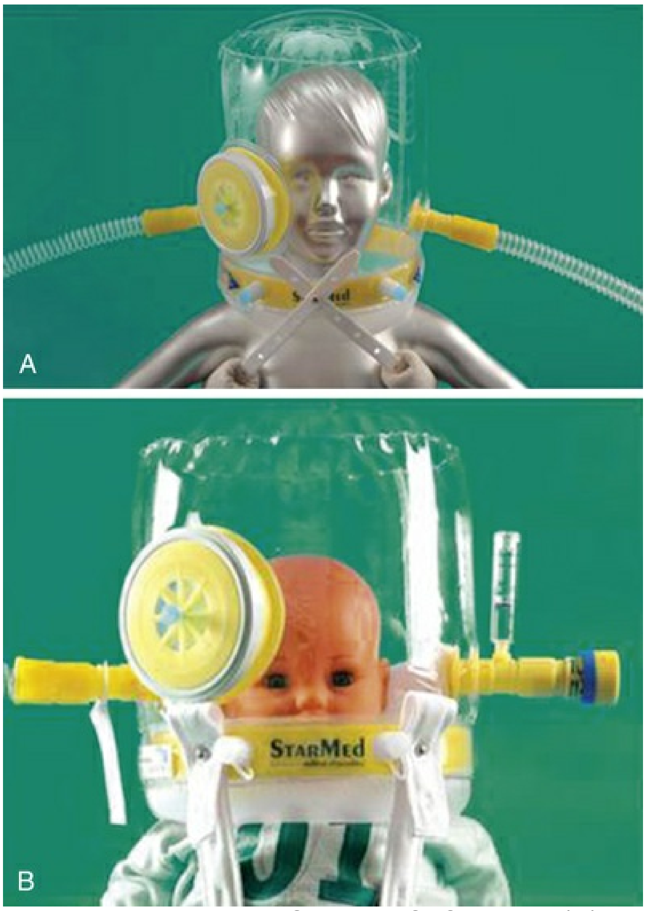

FIG. 58.6 Helmet or head hood. StarMed CaStar Ped (A) and StarMed CaStar Infant (B).

Mouthpieces: These are simple devices to be pursed between the lips for domiciliary mechanical ventilation (Fig. 58.7).

Equipment

A detailed description of the devices available for NIV at home is beyond the scope of this chapter, and the reader is referred to several excellent reviews.[148,149] This discussion focuses on the characteristics of positive pressure ventilators that can be used for providing NIV. Negative pressure ventilators are discussed elsewhere in the chapter. The ventilators that are used for NIV can be classified into three categories: (1) conventional ICU ventilators with a double-limb circuit without leak compensation, (2) devices with a single-limb circuit with leak compensation, and (3) devices that combine the previous two categories to include both leak compensation and having a double-limb circuit. Category 1 devices can only be used in the hospital. Category 2 and 3 devices can be used in both the hospital and at home. Examples of these devices would be any of the conventional ICU ventilators that can provide pressure support with positive end-expiratory pressure (PEEP) (Category 1), Respironics Bi-PAP (Category 2), and the Pulmonetics LTV ventilator (Category 3). The performances of these ventilators vary widely in delivered tidal volumes, air-leak compensation, response to simulated effort, inspiratory trigger, expiratory cycling, rebreathing, response to high ventilatory demands, and patient-ventilator synchrony.[150-150b] Category 1 or ICU ventilators operate with high-pressure gas sources with an oxygen blending system. Category 2 devices and 3 devices can operate without a high-pressure gas source. Bilevel ventilators do not have a blender, and therefore the delivered FiO_2 is unpredictable depending on the oxygen flow rate, ventilator settings, amount of leak, site of O_2 enrichment, and type of exhalation port.[151]

Optimizing Patient-Ventilator Interaction

Optimal patient-ventilator interaction requires that the ventilator be able to detect the patient's inspiratory efforts as quickly as possible and terminate inspiration (expiratory cycling) as close to the beginning of the patient's expiration as possible. Inspiratory trigger function differs significantly among the ventilators.[152-154] Factors affecting the inspiratory trigger function include trigger response to the inspiratory flow, leak-induced autotriggering, and pressure-time and flow-time waveform heterogeneity.[152-154] Strategies to optimize expiratory cycling include setting a suitable threshold for the inspiratory time and adjusting the expiratory cycling flow-threshold. Patients with obstructive lung disease tend to do better with high inspiratory flow, whereas patients with neuromuscular disease seem to do better with low inspiratory flows.[155] An adjustable backup rate is available in most modern ventilators used for NIV. It is particularly useful when sedation is used to improve patient compliance with NIV. Leaks around the interface reduce its effectiveness. Some amount of leak around the interface is expected with NIV. Complete elimination of air leak is not desirable as it comes at the expense of a very tight-fitting mask, which may lead to patient discomfort and skin breakdown. Ventilators differ in their capacity to compensate for leaks. One of the drawbacks of a large air leak is autotriggering. Humidification is important to prevent mucosal drying. Humidification can be provided using a heated humidifier, heat and moisture exchanger, or a pass-over humidifier.

Ventilator Settings

With CPAP, the level of CPAP is selected on the basis of the clinical needs. There should be relief of symptoms within 1 to 2 hours of application of CPAP. With short-term NIV, two strategies have been employed. One approach is to start with a high inspiratory pressure (about 20–25 cms H_2O). The goal of such an approach is for rapid relief of symptoms. If intolerant, a lower level that is tolerated is then selected. This approach is called the *high-low approach*. The other approach starts with a lower inspiratory pressure (about 8–10 cms H_2O) and gradually increases to produce relief of symptoms. The aim of this approach is to maximize patient comfort and tolerance. This is called the *low-high approach*. Within the first 1 to 3 hours, subsequent adjustments may be necessary depending on the patient response. Expiratory pressure is used routinely during short-term NIV. Maximal fraction of inspired oxygen (FiO_2) with bilevel ventilators is usually about 45% to 50%. If a higher FiO_2 is required, and endotracheal intubation is not indicated, then an ICU-type ventilator may be used.

Complications and Concerns During Short-Term Noninvasive Ventilation

Aerophagia and gastric distention can occur with NIV. The higher the pressures used, the greater the chance of gastric distention. Regurgitation of gastric contents and aspiration into the lungs are major concerns with the use of an oronasal, total face masks, and a helmet. Close monitoring is necessary to prevent aspiration. A nasogastric tube to keep the stomach decompressed is necessary in these acutely ill patients. Pressure sores related to the masks are the other major concern. It should be possible to pass one or two fingers between the headgear and the face. Care should be taken to avoid fitting the interface too tightly. A spacer with soft padding can reduce the incidence of pressure sores on the face.

Circuit and CO_2 Rebreathing

Single-limb circuits that are employed with bilevel ventilators can result in significant CO_2 rebreathing. All single-limb circuits have an exhalation port that is placed close to the patient interface through which exhaled gas will escape. If the exhaled gas flow exceeds the rate of escape through the exhalation port, exhaled air is rebreathed with the next inspiration. This results in significant CO_2 rebreathing and can cause hypercarbia. Rebreathing also depends on the level of EPAP, location of the exhalation port, and design of the exhalation port. Earlier devices had significant CO_2 rebreathing of the exhaled air, especially if the EPAP levels were set too low. In the newer designs, this problem has been largely minimized. The closer the exhalation port to the patient interface, the lower the rebreathing of CO_2. In fact, if the exhalation port is located in the mask itself, it results in the lowest amount of CO_2 rebreathing. Dual-limb circuits eliminate the risk of rebreathing.

Ventilator Settings

Similar to short-term NIV, the ventilator settings must relieve patient symptoms. The approach that is generally recommended for long-term NIV is the low-high approach with gradual increase in support. A backup rate sufficiently high to control breathing nocturnally can rest the respiratory muscles and prevent apnea, especially in patients with neuromuscular disease. NIV can be provided both intermittently and continuously. There has been an increase in the continuous use of NIV, especially in patients with neuromuscular disorders. This has resulted in prolonging survival in these patients.

Monitoring of Patients With Long-Term Noninvasive Ventilation

Monitoring patients who are on long-term NIV requires an assessment of their respiratory function. Pulse oximeters are useful in detecting hypoxemia especially during sleep. End-tidal CO_2 monitors are only used in the clinic or hospital. Treatment of sleep-disordered breathing improves the quality of life and may prolong survival. Polysomnography may be required to document sleep disorders but is more expensive than nocturnal pulse oximetry. If a patient has bulbar weakness or severe obesity, there may be obstruction of the upper airway or obstructive sleep apnea in addition to sleep hypoventilation. Both problems are treated with nocturnal ventilation.

Negative Pressure Ventilation

Design and Modes of Negative Pressure Ventilators

All negative pressure ventilators have a chamber in which subatmospheric pressure is generated and a pump that generates this pressure. The chamber may cover only the chest and the upper abdomen (cuirass, Fig. 58.8) or all the extracranial portions of the body (tank respirator [Fig. 58.9], isolette, or a body suit). The tank respirator has both the chamber and pump in one unit. In all other cases the two units are separate. The cuirass can be prefabricated or custom designed to fit the contours of the chest. Custom designed cuirasses are especially useful in patients with skeletal or spinal deformities. All body suits fit over a hard shell similar to the cuirass placed over the chest and upper abdomen. Most negative pressure pumps in use today are pressure cycled. Some volume-cycled pumps have been used, but their use has been limited because the pump cannot compensate for the variable amounts of air leak.

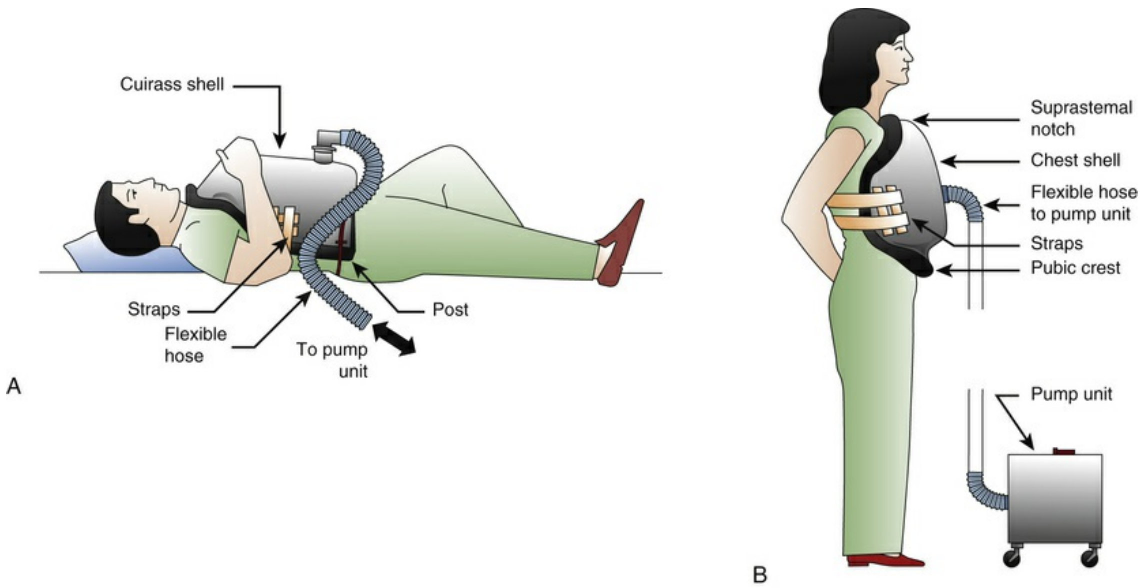

FIG. 58.8 Cuirass ventilator. During inspiration, a negative pressure is created in the cuirass shell using an external pump. Expiration (A) can be either passive or assisted with positive pressure (so-called biphasic ventilation). This can be applied in both the supine (A) and nonsupine (B) positions.

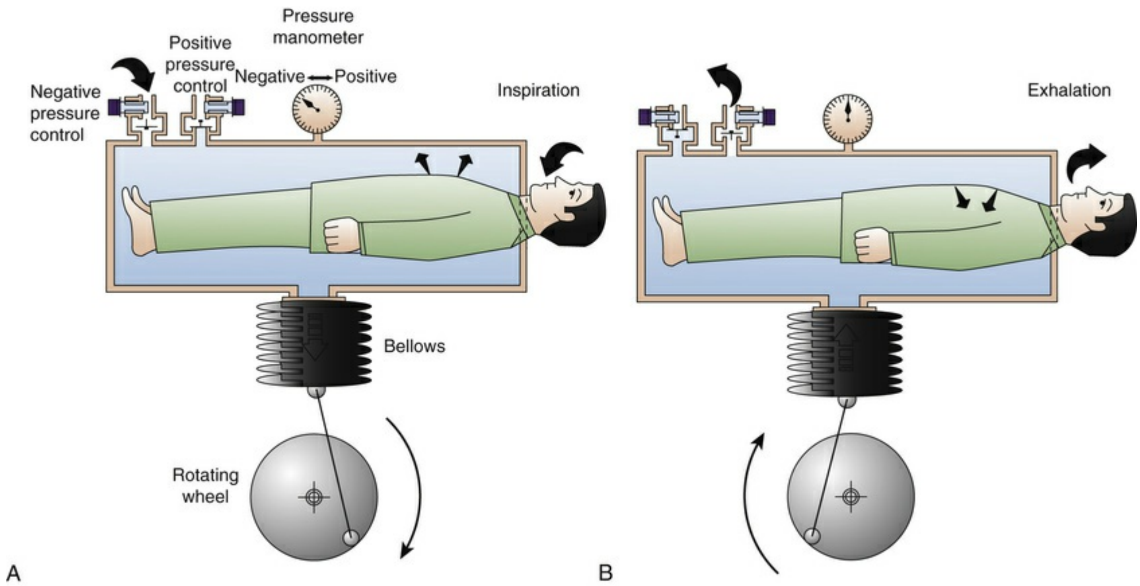

FIG. 58.9 Tank respirator. During inspiration (A), a negative pressure is created in the chamber using a bellows system (shown in figure) or a piston. Expiration (B) can be either passive or assisted with positive pressure (so-called biphasic ventilation).

Tank/Whole Body Ventilator

Most of the modern tank ventilators are either made of aluminum or plastic and have separate rotary pumps. Older ventilators had bellows pumps either separately or incorporated into the unit.[7,8] There is a mattress inside the chamber on which the

patient's body rests and a head and neck rest that are outside the chamber. Most models have windows and portholes that allow observations of the patient and access to the patient as well. In some models, the head or feet can be raised, as well as tilting of the whole body. One advantage of the tank respirator is that it does not need to be designed to fit each patient. It requires only one effective seal at the level of the neck. The disadvantage is that it is difficult to access the patient. Aspiration of material from the pharynx into the trachea and bronchi may occur, especially with swallowing dysfunction. The tidal volume is directly proportional to the peak negative pressure within the chamber.[156]

Isolette Ventilator

An isolette-type respirator is a negative pressure ventilator consisting of two Plexiglas chambers, one for the body and one for the head.[157,158] The two chambers are connected by an opening equipped with a neck sleeve. The infant's body is placed on a mattress in the body chamber with the neck placed in the opening between the two chambers. The head rests on a head rest. When the neck sleeve is gently closed around the neck to obtain a relatively tight seal with all the openings in both chambers being closed, negative pressure ventilation can be instituted. The depth of ventilation is controlled by the peak inspiratory negative pressure. Ventilator rate and the inspiratory/expiratory ratio are selected by adjusting the appropriate controls.[157,158] Humidified oxygen is delivered by a face mask or into the head chamber. The infant's body temperature can be controlled using servo control regulation. In ventilators using synchronized modes, a self-triggering device that detects either inspiratory flow or breathing movements is usually attached to the patient.

Cuirass Ventilation

Theoretically, a cuirass that covers only the chest should be easier to use than the tank ventilator. Unfortunately, standard sizes may fit poorly and fail to provide an airtight seal around the chest. Therefore many of the cuirasses may have to be custom fit for use so that the cuirass should not only seal the chest without leaks but also enable the anterior abdominal wall to be free to expand during inspiration.[159,160] Customized cuirasses are usually constructed from a cast of the patient's chest.[159,160] The cuirass is made of a synthetic material (Vitrathene or fiberglass), which makes it light and can be made airtight by padding the edges and covering it with airtight material such as neoprene. Sometimes, a back strap may be necessary to maintain an airtight seal between the cuirass and patient. Development of pressure sores at the points of contact between the cuirass and the patient is a disadvantage that needs to be monitored. Similar to the tank ventilator, the tidal volume achieved with a cuirass is proportional to the peak negative pressure within it.

Hayek Cuirass Ventilator

The Hayek oscillator is currently the most versatile cuirass-type negative pressure ventilator (Fig. 58.10). The cuirass is a lightweight, flexible chest enclosure with large soft seals to fit around the chest and abdomen. It rests on either a backplate or flexible cushion forming an airtight enclosure around the chest and abdomen. This is in contrast to previous cuirass designs, which were heavy, bulky, and

nontransparent. There is a range of sizes for patients ranging from preterm infants to adults. The ventilator unit is attached to the cuirass and is capable of biphasic ventilation. The unit is capable of providing ventilation with frequencies ranging from 6 breaths/min to 20 Hz. This machine can behave as a conventional negative pressure ventilator at frequencies to 2 Hz. Tidal volume increases in proportion to the negative pressure span generated within the cuirass, and minute ventilation is related to the tidal volume and frequency. At a frequency above 2 Hz, however, the Hayek oscillator behaves more as a high-frequency oscillator and oxygenation is achieved largely by diffusion. Three frequencies of up to 15 Hz can be obtained with this machine, and frequency, inspiratory, and expiratory pressures and I:E ratio are dialed in for individual patients. Adjusting the expiratory pressure permits ventilation above, at, or below the patient's FRC.

FIG. 58.10 Hayek cuirass ventilator. The chest cuirass is made of flexible plastic. This ventilator is capable of conventional negative pressure ventilation, as well as high-frequency chest wall oscillations.

Jacket Ventilation

The first effective jacket ventilator was the Tunnicliffe jacket, developed in the 1950s.[161] The design consists of an airtight synthetic garment with an inner framework made of metal or plastic. Most of the models cover the chest and abdomen and end at a level just below the hips (Fig. 58.11). Though several sizes are available, they are still too large for infants and children. They are also not quite effective in patients with skeletal abnormalities. A pump intermittently evacuates the air within the jacket similar to that used in a cuirass ventilator. The developed tidal volumes are usually smaller than that of a tank respirator. The most commonly used are the Tunnicliffe jacket, Lifecare PulmoWrap, and Lifecare Numo Garment.

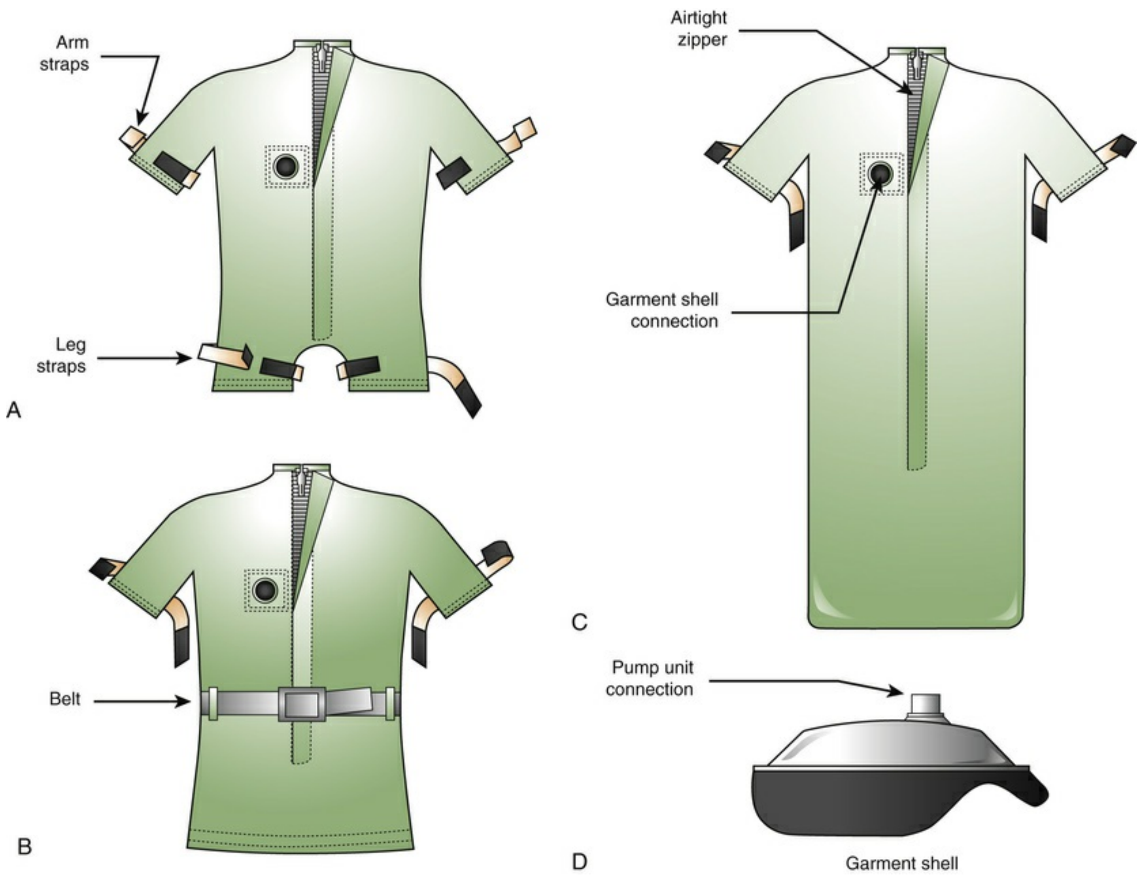

FIG. 58.11 Jacket ventilation. Jackets of different sizes are shown with an inlet port to connect the ventilator tubing. A, B, and C are jackets with seals at different locations. D is the garment shell with a pump connection.

Current Modes

At present, there are four modes of negative pressure application: (1) cyclical negative pressure, (2) negative/positive pressure, (3) CNEP, and (4) negative pressure/CNEP. Cyclical negative pressure ventilation refers to a mode where the ventilator generates the preset subatmospheric pressure during inspiration while expiration is passive. Negative/positive pressure ventilation refers to a mode that is a combination of negative pressure during inspiration with positive pressure during expiration. CNEP refers to a mode where a constant subatmospheric pressure is provided throughout the respiratory cycle and the patient breathes spontaneously. Negative pressure/CNEP refers to a mode where negative pressure inspiratory cycles are superimposed on CNEP. Additionally, some ventilators provide an inspiratory assist mode. Respiratory synchronized mode, available in the RTX Respirator, allows full synchronization using the patient's inspiratory and expiratory efforts.

Table 58.6 shows the indications, advantages, disadvantages, contraindications, and clinical side effects of negative pressure ventilation.

TABLE 58.6

Indications, Advantages, Disadvantages, and Contraindications of Negative

Indications
1. Parenchymal lung disease Respiratory distress of the newborn Interstitial pneumonias Acute respiratory distress syndrome Acute pulmonary edema 2. Respiratory pump failure Poliomyelitis Neuromuscular diseases Skeletal deformities Persistent flail chest deformity 3. Cardiovascular disorders After Fontan-type operations Repair of total cavopulmonary connection Tetralogy of Fallot Phrenic nerve palsy after pediatric cardiac surgery
Advantages
1. Avoidance of intubation or tracheostomy 2. Preservation of physiologic functions such as speech, cough, swallowing, and feeding 3. Allows fiberoptic bronchoscopy to be performed without disconnection from the ventilator 4. Promotes venous return by creating negative intrathoracic pressure
Disadvantages
1. They are noisy 2. Access to patient is difficult 3. Tank ventilators produce abdominal pooling of blood resulting in hypotension (tank shock) 4. Regulation of inspiratory-expiratory ratio is difficult (more recent ventilators such as the Hayek negative pressure ventilator allow for regulation of inspiratory-expiratory ratio and application of negative end-expiratory pressure) 5. Difficult to sterilize 6. Lack of protection of the upper airway, especially in unconscious patients or those with bulbar dysfunction 7. Upper airway obstruction can be minimized with an oral airway 8. Difficulty in achieving an adequate seal 9. Discomfort
Contraindications
1. Gastrointestinal bleeding 2. Rib fracture 3. Recent abdominal surgery 4. Uncooperative patients 5. Sleep apnea syndrome 6. Neurologic disorders with bulbar syndrome Clinical Side Effects 1. Tiredness 2. Musculoskeletal pain or tightness 3. Esophagitis 4. Rib fractures and pneumothorax 5. Impaired sleep quality 6. Poor compliance

Summary

NIV is a viable alternative to invasive mechanical ventilation in children. NIV can be used for both short-term and long-term needs to treat respiratory failure. Selection of patients is crucial to ensure success with NIV.

CHAPTER 59

Extracorporeal Life Support

Heidi J. Dalton, Tom Preston, Hanneke IJsselstijn

PEARLS

- Venovenous cannulation for extracorporeal membrane oxygenation (ECMO) is currently preferred for patients with adequate cardiac function and is used in over 50% of reported children.
- Venoarterial access for ECMO remains the most common cannulation technique for patients with cardiac dysfunction.
- In venoarterial ECMO, desaturated venous blood is drained from the body and reinfused into a large artery after being oxygenated in the ECMO circuit.
- Venovenous ECMO differs from venoarterial ECMO in that blood is both withdrawn and returned into the venous circulation of the patient.
- The use of ECMO in patients with neonatal respiratory failure has decreased as new methods of support, such as inhaled nitric oxide, surfactant, and high-frequency oscillation, have been developed.
- As experience with ECMO support in older patients has grown, expansion to clinical situations such as cancer, sepsis, burns, and trauma has occurred.
- One quickly expanding area of extracorporeal support is as a means of resuscitation in cardiac arrest (extracorporeal cardiopulmonary resuscitation).
- Improvements in extracorporeal pumps, cannulae, circuitry, and oxygenators are making ECMO easier to implement and potentially safer.

Aided by the discovery of heparin in 1916 and by advances in the technology of membrane oxygenators,[1] extracorporeal life support has changed dramatically since the early 1950s, when John Gibbon first used a machine of his own design to provide extracorporeal life support for a cat whose pulmonary artery was occluded with a clamp.[2] Early experiences with the use of cardiopulmonary bypass for operations on the heart were mixed, but as experience and technology have continued to advance, the field of cardiopulmonary bypass has expanded at a rapid rate.

As experience with bypass techniques in the operating suite grew, investigation of the use of extracorporeal support of patients with cardiopulmonary failure outside

the operating room began.[3-6] Infants with severe respiratory disease or pulmonary hypertension were among the groups for whom use of a temporary cardiopulmonary bypass system seemed appropriate. This technique of modified cardiopulmonary bypass came to be known as “extracorporeal membrane oxygenation” (ECMO).[7-11] Although premature infants had an unacceptably high incidence of intracranial hemorrhage as a result of systemic heparinization, infants of more than 35 weeks' gestation with respiratory failure were successfully supported with ECMO. An abandoned infant with severe hypoxemia, named Esperanza (meaning “hope”) by her caregivers, was among the first to be treated with ECMO by Bartlett in 1976. Today, Esperanza is a grown woman with children of her own.

Efforts to organize and collate data on patients treated with ECMO resulted in the formation of the Extracorporeal Life Support Organization (ELSO).[12] In 2014 ELSO celebrated its 25th anniversary. This largely volunteer network of physicians, surgeons, nurses, respiratory therapists, and all those with an interest in extracorporeal life support comprises more than 130 centers and contains data on more than 60,000 patients treated with extracorporeal life support throughout the world. The rise in new ECMO centers and support of older children and adults is exciting, but unfortunately many patients who receive ECMO are not reported to ELSO. This hampers efforts to obtain a fully accurate description of ECMO use and outcomes throughout the world.

As more patients have been treated and techniques have been refined, ECMO procedures and management of patients have evolved to the point that ECMO now can be offered to patient groups previously excluded from consideration.[13-19] The decision regarding when a patient should be treated with ECMO remains empirical and is often based on clinical judgment and case discussion with involved clinicians and family. Similarly, although there is little complete standardization of ECMO circuit design, cannulation technique, and patient management, the general principles are fairly constant. Guidelines for ECMO center training, equipment selection, and patient selection and management have been developed by expert consensus and are posted on the ELSO website (www.ELSO.org). Although the guidelines are fairly general, the expectation is that they will enable more standardization of practice in the future. The information in this chapter represents general practice, the authors' experience, and a review of the literature. For more detailed information regarding extracorporeal life support, the reader is directed to the excellent text regarding this subject published by the ELSO organization.

Materials and Methods

Cannulation Techniques

Several modes of ECMO, or extracorporeal life support (ECLS), as it is also known, have been developed that differ according to cannulation site and minor physiologic principles.[20-31] However, the basic circuit is similar for all modes. Cannulation may be venoarterial or venovenous. Venoarterial access has been used most commonly in the past and will be discussed first.

Cannulation for Extracorporeal Membrane Oxygenation

Venous Access

In venoarterial ECMO, desaturated systemic venous blood is drained from the body and reinfused into a large artery after being oxygenated in the ECMO circuit (Fig. 59.1). The right atrium is the usual site accessed for ECMO cannulation. The internal jugular (IJ) vein is a large vessel with a fairly short, straight course to the right atrium and thus is preferred during cervical cannulation. To augment cerebral venous drainage in patients who undergo cannulation via the right IJ vein, some centers also place a smaller cannula retrograde in the vessel to the level of the jugular venous bulb at the base of the skull. This catheter can facilitate cerebral venous drainage and provide a means of monitoring jugular venous oxygen saturation. Some clinicians believe that monitoring jugular venous saturation provides information on the adequacy of oxygen delivery to the brain and that it is valuable during ECMO, although this practice is relatively controversial. Reports of an increase in venous drainage via the retrograde cannula of up to one-third have been noted, although the practice seems relatively infrequent in most centers.[21,22] The retrograde catheter is connected by a Y adapter into the larger venous drainage line.

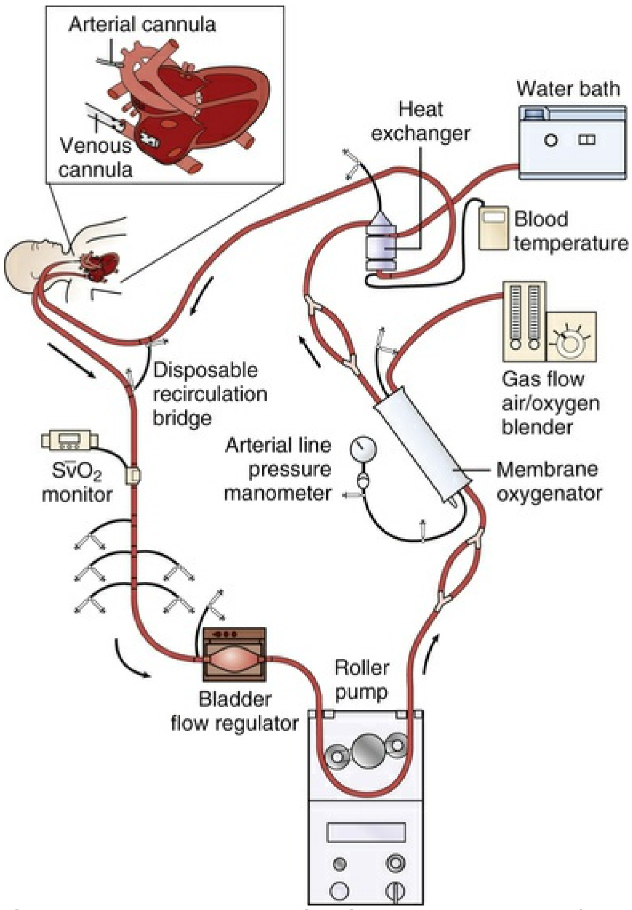

FIG. 59.1 Cervical venoarterial ECMO with roller pump/silicone lung.

In older children and adults, the femoral vessels can be used for cannulation. Venous access is obtained from the femoral vein into the inferior vena cava (IVC), or the cannula can be advanced further up the IVC to the right atrial/IVC junction. Although femoral vein cannulation diverts less venous return to the pump than a

catheter positioned in the right atrium, the amount of blood drained is often adequate to meet the needs of the patient. Femoral cannulation is generally restricted by age, vessel size, and to patients who are at least 15 kg. For patients with femoral venous access who exhibit venous stasis or obstruction of the extremity distal to the cannula, a similar catheter to that used for jugular venous drainage can be directed distally to facilitate decompression of the leg and augment venous return. This catheter is then connected by a Y adapter into the venous drainage line of the ECLS circuit. Compartment syndrome from venous stasis in femoral venous cannulation has been described, and thus careful monitoring of the extremity is mandatory.

In patients who undergo cannulation via the mediastinum, the venous cannula is often placed directly into the right atrial appendage. Other vessels, such as the subclavian or axillary vessels, have been associated with limb perfusion abnormalities or difficulties with adequate blood flow in the past. New cannulas with better flow dynamics or use of side grafts onto vessels that do not occlude distal blood flow may allow use of vessels that have been previously avoided.

Arterial Access

Access is obtained for cervical venoarterial ECMO by cannulating the right carotid artery and advancing the cannula to the arch of the aorta. Care must be taken not to position the end of the cannula close to the aortic valve, because this position may result in aortic insufficiency induced by the high-velocity blood flow returning from the ECMO circuit and being directed toward the aortic valve leaflets. Alternatively, if the arterial cannula is advanced too far down the aortic arch, it can occlude blood flow to the left carotid artery and the brain. Cervical venoarterial ECMO is associated with risk of emboli from the ECMO circuit into the brain and potential risk for neurologic abnormalities or stroke later in life. Sixty-four percent of patients <18 years of age reported to the ELSO registry from 2007–2008 received cervical cannulation, with 66% of these patients comprising neonates. Other sites included the femoral artery in 15% and the aorta in 32%. Neurologic injury occurred in 22% of patients and cervical cannulation independently increased odds of neurologic complications (odds ratio [OR] 1.4, 95% confidence interval [CI] 1.01–1.69). No interaction between age and cannulation site was noted.[23-26]

Use of the femoral artery for access during venoarterial ECMO requires careful monitoring of upper body oxygenation to avoid the *red lower body, blue upper body* syndrome. If a long femoral artery cannula that reaches the thorax is used, good oxygenation to the upper body is assured, but resistance to blood flow is high. Most often, a short femoral artery cannula is used (18 cm), which normally sits in the iliac vessels. The amount of arterial return reaching the upper body, heart, and brain in this mode of ECMO is dependent on antegrade flow out of the native left heart and the retrograde flow from the ECMO arterial return. In patients with severe cardiac dysfunction, arterial return from the ECMO circuit flows further up the aorta and may predominate. In patients with good cardiac function, the majority of upper body arterial flow may be from native left heart ejection. Arterial flow from low-lying ECMO cannulas with good native heart function may thus preferentially flow to the lower body. This arterial flow will mix with venous return from the lower body before the oxygenated blood flows through the cardiopulmonary circuit and out the aorta. In patients with impaired gas exchange, the amount of venous mixing prior to reaching the ascending aorta reduces the amount of oxygen that is delivered

to the upper body (heart and brain). Thus the PaO_2 and arterial oxygen saturations in the upper body are lower than that obtained with cervical venoarterial ECMO. One study of various configurations of ECMO in an animal model of respiratory failure noted that venous saturations in the superior vena cava during femoral venous and arterial cannulation only reached 40%. Successful use of ECMO has been achieved, however, with this mode, and it is extremely common in adults, especially those placed on ECMO during arrest. Monitoring upper body oxygenation with a pulse oximeter, near infrared spectroscopy, or other measures is recommended to assess the amount of oxygenated flow getting to the head during this mode of ECMO. Echocardiography often can determine the extent of retrograde aortic flow versus native heart ejection.

One method to improve upper body oxygenation in the event of hypoxia with femoral arterial cannulation is to add another cannula in the right internal jugular vein and Y this into the return portion of the ECMO circuit. This will direct some oxygenated blood into the right heart and improve overall upper body saturation. This so-called hybrid model works well in many reports, although flow to both the femoral artery and the right IJ cannula must be monitored to ensure that adequate flow is directed to both sites and avoid thrombosis from stagnant blood flow.

Femoral arterial cannulation also can be associated with impaired flow to the distal limb and resultant ischemia.[27,28] A small *feeder* cannula can be directed distally down the leg artery and then connected by a Y adapter into the arterial cannula to improve perfusion. Additionally, placement of a 14-gauge catheter into the posterior tibial artery that is then connected by a Y adapter into the arterial side of the ECMO circuit has been reported. Ischemia and the need for amputation with femoral artery cannulation occur even with such precautions, therefore meticulous attention to limb perfusion is required to prevent this complication.[27,28] Establishing a graft onto the femoral artery through which the cannula is inserted or ultrasound-based sizing of the femoral vessels and use of a cannula that will not completely occlude the femoral artery have also been suggested to limit risk of ischemia. Side graft techniques have also been used successfully to allow ECMO support via subclavian or axillary vessels.[29]

In mediastinal cannulation, the arterial return cannula is usually placed into the aortic arch under direct vision. During mediastinal cannulation, patients with severe left ventricular dysfunction who cannot open the aortic valve to eject blood often have a left atrial venting catheter inserted to allow decompression of the left heart. This technique prevents pulmonary venous hypertension, which can lead to severe pulmonary edema or hemorrhage. This catheter can be connected by a Y adapter into the venous drainage of the ECLS circuit to provide adequate left heart decompression.[30,31]

Patients with intact sternums who require left atrial decompression often are taken to the cardiac catheterization suite for a blade atrial septostomy that then allows the left heart to decompress into the right atrium and the blood to be drained into the venous ECMO cannula.[31] Experience with use of an Impella device to provide left heart drainage or use of an intraaortic balloon pump (in larger patients) has also been successful.

The primary modality to verify proper cannula position has traditionally been chest radiography; however, use of echocardiography is known to be more accurate and should be considered the gold standard for evaluation of cannula placement.[32]

Venovenous Extracorporeal Membrane Oxygenation

Venovenous ECMO differs from venoarterial ECMO in that blood is both withdrawn and reinfused into the patient's venous circulation (Fig. 59.2). Cannulation can be introduced via either the cervical or femoral vessels.[33] Currently several types of multiple-lumen, single cannulas exist. One such cannula, manufactured by Origen Inc. (Austin, Texas), is available in sizes from 13 to 32 Fr and can support patients of all sizes. This cannula is placed into the right IJ vein and requires only one surgical site. The drainage and infusion lumens in this cannula are separated by a distance of a few centimeters. Reinforcement of the drainage lumen now prevents collapse of this lumen, which had limited its effectiveness with centrifugal pump systems in the past. Careful placement and orientation of the cannula can reduce recirculation of reinfused blood from the ECMO circuit, although some amount of recirculation (which will be discussed later in further detail) always occurs. Another cannula, especially popular with adults and larger children, is manufactured by Avalon Inc. (Maquet). It is also available in sizes from 15 to 31 Fr and is able to obtain flow rates to support even large adult patients. This cannula has two drainage lumens, one of which is positioned in the IVC and one in the superior vena cava. A reinfusion port that sits between the two lumens is directed at the tricuspid valve when placed properly—thus limiting recirculation of oxygenated blood. Placement of this cannula requires meticulous assessment with echocardiography or fluoroscopy for optimal performance. Although experience with the Avalon cannula has been good, especially among adolescents and adults, late cardiac perforation or difficulty in maintaining proper placement has been reported in children (especially infants). Reconfiguration of the distal IVC port in the 13-Fr cannula has been completed, but its effectiveness is not yet well documented. Time will tell if the advantages of this cannula outweigh its increased cost.

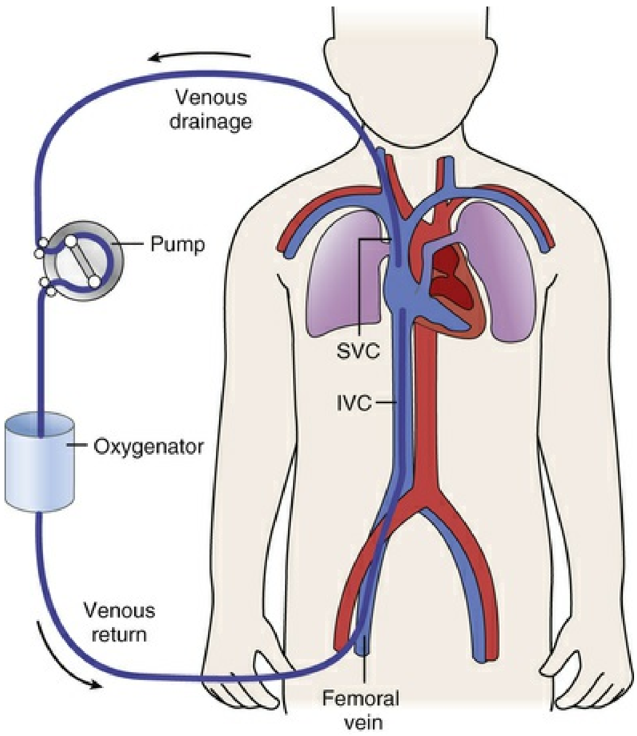

FIG. 59.2 Venovenous ECMO with two site cannulas.

Venovenous ECMO also can be provided via two (or more) separate access sites. The right IJ and femoral vein provide access in the majority of patients. Patients with venovenous cannulation may have venous blood drained from the right atrium via the IJ vein or from the IVC via the femoral vein. Although more venous drainage usually can be obtained from a cervical cannula (which is usually shorter and larger than a cannula that can be placed into the femoral vein), the femoral site often may prove adequate and draining from the femoral vessel and reinfusing into the IJ results in less recirculation. Older children and adults also may undergo bilateral femoral cannulations, with one cannula placed into the high IVC and the other ending in the low IVC or iliac vessels (see Fig. 59.2).

Percutaneous Cannulation

Although the historical approach to vessel access has been via an open procedure with placement of cannulas under direct vision, kits for percutaneous placement now exist in many sizes. These kits use a modified Seldinger technique with obturators increasing in size to dilate the vessel. Once the appropriate size is reached, the cannula is passed into the vessel over the largest obturator.

Percutaneous cannulation carries with it the inherent risks of potentially tearing a large vessel during cannulation. Although percutaneous cannulation in some centers is performed by nonsurgical personnel, surgical backup to perform an immediate cutdown for control of bleeding from a disrupted vessel may be needed. Despite the obvious fear of vessel disruption, this complication occurs infrequently. In one series of 100 patients who were cannulated by nonsurgical personnel, only 2 vascular complications occurred. Both were associated with mortality.[34] Percutaneous cannulation avoids the need for an open surgical site, thus decreasing surgical site bleeding and risk of infection.

Venous Reservoir and Venous Saturation Monitor

Use of semiocclusive pumps requires a venous reservoir, called the *bladder,* that sits at the lowest point of the ECMO circuit and allows blood to collect and be drawn from it to the pump head. It also acts as an air trap and normally has access ports to allow aspiration of any air collected in the bladder chamber. The bladder can be used as a servoregulating device that helps to match forward flow to venous return. Advances in bladder technology resulted in the Better Bladder (Circulatory Technology Inc., Oyster Bay, New York), which is a piece of collapsible tubing encased in a hard shell. Changes in venous return cause the tubing to contract. This device helps servoregulate flow and can be used with either semiocclusive or centrifugal pumps. Servoregulation by monitoring of direct negative and positive pressure within the ECMO circuit has eliminated the use of the bladder in some centers, although most still incorporate some sort of “bladder” within the circuit.[35,36]

Another important feature of the ECMO circuit is the venous saturation monitor that is placed along the venous drainage line. Most new pump systems incorporate this into their monitoring apparatus. Transonic flow probes can provide venous saturation monitoring and may be used to provide additional information. Monitoring venous saturation over time gives information regarding the balance of oxygen delivery and extraction. Use caution when interpreting venous saturation in

the presence of left atrial drains or left-to-right intracardiac shunts (which allow oxygenated blood returning from the lungs to be directed into the venous drainage line), as observed venous saturation may not reflect tissue levels of venous saturation but be falsely elevated. Venous saturation should be monitored at a site proximal to entry of oxygenated blood into the circuit.[36,37]

Types of Pumps and Oxygenators

Roller-Head Pumps

The majority of ECMO prior to 2011 was performed using a roller-head semiocclusive pump.[38,39] Venous blood is siphoned via gravity to the roller heads, which are enclosed in a box (the pump housing). Compression of the raceway tubing advances blood forward at high pressure to the membrane lung (if gas exchange is required), from which it is returned to the patient. The gravity siphon, the need to reposition tubing within the raceway to avoid rupture, and the need for pressure monitoring with multiple access points within the circuit combine to require a large priming volume. This increases the exposure to blood products and the associated inflammatory response from contact with the artificial surface of the circuit. Hemolysis from red cell destruction within the raceway or other areas of turbulent flow in the circuit may also occur. Roller pumps generate high pressure in the circuit distal to the raceway/roller heads. Thus acute interruption to forward flow as may occur with kinking of the arterial cannula or elevated resistance to blood flow on the high-pressure side of the circuit can result in an immediate and potentially lethal circuit rupture. Monitoring of the high-pressure side of the ECMO circuit is universal, with critical high limits for arterial line pressure determined based on tubing size and pump flow. Pressures below 300 to 350 mm Hg are desired, and safety mechanisms will stop the ECMO pump if line pressure limits are exceeded. Many centers use filters in the ECMO circuit prior to blood return to the patient, which can help detect air bubbles or trap debris. While using a filter seems practical, in reality these devices may be so sensitive that they result in many episodes of stopping ECMO to check alarms or maintain the filters. A more complete description of roller-head ECMO support can be found in prior editions of this chapter.

Newer pumps may provide pulsatile flow. The nonpulsatile nature of venoarterial ECMO flow has been implicated in the renal dysfunction sometimes noted in patients treated with venoarterial ECMO. The pulsatile flow of the newer pumps has yet to be effectively linked to native heart ejection, although this remains a goal.[40,41]

Centrifugal Pumps

Many centers have transitioned to centrifugal pumps for ECMO support.[42] Although older models were plagued with hemolysis at the low flows that infants and children require, newer devices now employ small pump heads, which may be magnetically levitated or function via bearings that are low resistance, extremely durable, and create less heat, which may lessen risk of hemolysis. Although both roller and centrifugal pumps can create high negative pressure on the venous inflow side, centrifugal pumps only create forward flow if downstream pressure is lower than that in the pump head. Thus occlusion of the postcentrifugal pump circuit will not generate high pressures than can result in tubing rupture as can occur in

semiocclusive, roller-head systems. Loss of venous return with continuous rotation of either roller-head or centrifugal pumps results in generation of high negative pressure in the ECMO tubing that can lead to hemolysis and cavitation as air is drawn out of solution. The collapse of the tubing and cannula that can be induced by high negative pressure also can lead to damage of the endothelium of the affected vessel or the right atrium. To protect the patient as venous return is lost and negative pressure develops, a signal is sent to the pump head that causes it to slow down or stop until adequate venous return is achieved. Older versions of the servoregulation system stop the pump whenever venous return diminishes and then restart it when venous return is adequate. This on/off action of servoregulation has been shown to result in acute changes in cerebral blood flow in patients who have undergone cannulation via the cervical route, which may be harmful. Centrifugal devices contain a magnetically controlled spinning head. Blood enters at the inner apex and is propelled tangentially to the outer wall of the pump head. There it is expelled into the circuit. In the past, hemolysis has limited the use of centrifugal pumps, especially in small children. The longer blood sits in the centrifugal head and the faster the head spins, the more hemolysis will be created. It is also postulated that as clots develop in the membrane oxygenator over time and increase outflow resistance, hemolysis worsens in the rotor head. Centrifugal pumps may also create microemboli, which can reach the patient if they are not trapped in the membrane lung. Newer pump designs have small heads that require little priming volume. Technical advances in “spinning” the head may also reduce hemolysis. New low-resistance hollow fiber membrane lungs allow easy propulsion of blood from the centrifugal device and are a major reason that centrifugal pumps have become so popular for patients of all ages.[45,46]

Blood flow to the centrifugal head is augmented by the suction effect of the spinning pump head and thus is not as dependent on gravity drainage as are roller-head pumps. Thus centrifugal pumps can be placed at any level as long as it is below the level of the patient's heart, which makes transporting the patient easier than with roller-head devices. Circuit length can also be reduced, which allows for smaller priming volumes and the potential for less exposure to blood products. The active suction effect of centrifugal heads can create levels of negative pressures as high as −200 to −700 within the venous inlet tubing. Monitoring of venous pressure with alarm limits to signal when excessive negative pressure is occurring is common in most centers. Setting an appropriate venous line or inlet pressure is an important part of circuit management but seems frequently misunderstood. Optimal servoregulation alarms or interventions require a number of factors that should be taken into consideration. The most important fact is that the total resistance on the venous side of the circuit is the sum of the resistances. The major contributor to this negative pressure is the pressure drop across the venous cannula. Most manufacturers provide pressure drop curves for each of their cannula across a range of flow rates (Fig. 59.3). Although these curves are created using water instead of blood, and thus do not represent the effect of viscosity of blood, they provide a suitable surrogate for the resistance induced by the cannula. Selecting a cannula that will provide the expected blood flow at a pressure drop of less than 100 mm Hg is recommended[47] (see Fig. 59.3). Pressure drops greater than 100 mm Hg will increase the risk of hemolysis. Another factor to consider is that exposure of the right atrium to pressures more negative than 20 mm Hg can damage the intima. Taking these two

points into consideration, if the venous cannula chosen to provide the expected blood flow rate has a pressure drop of 40 mm Hg from inlet to outlet, the venous servo limit should be set at −60 mm Hg to protect the right atrium from damage and provide adequate blood flow. Thus the venous pressure limit to be set will vary from patient to patient. Clinicians also vary as to where best the venous pressure should be measured—at the junction of the catheter to the circuit tubing, which will reflect negative pressure closest to the heart, or at the pre–pump head site, which reflects the most negative pressure within the total circuit.

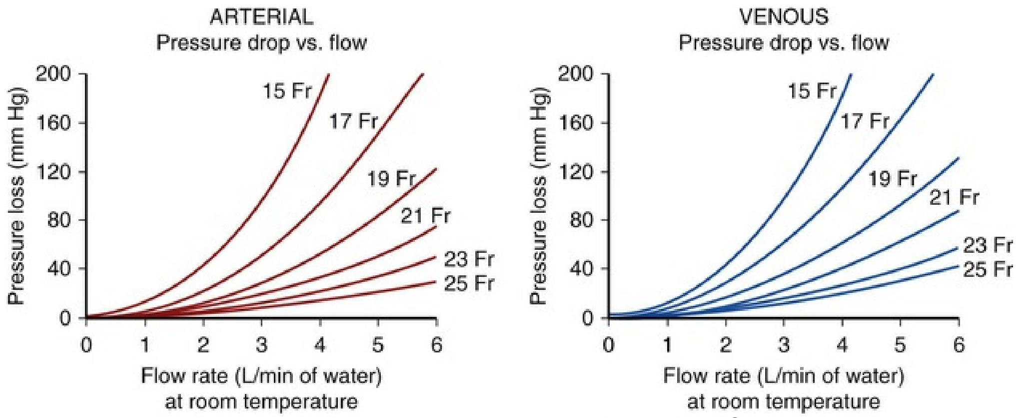

FIG. 59.3 Pressure drop across cannulas based on flow. (Reproduced from Medtronic, Inc., with permission.)

Monitoring venous return and understanding the function of centrifugal pumps are keys to safe and appropriate use of this form of support. Another advantage of centrifugal pumping devices is that air and debris are trapped within the vortex of the pump head and may be less likely to embolize than with roller-head circuits. This advantage is countered by some reports that centrifugal pumps generate more microbubbles than do roller-head devices. A publication examining causes of hemolysis noted that the direct interaction of blood with air and high negative pressure (such as occurs with cardiotomy suction during bypass surgery) resulted in the greatest amount of hemolysis. Centrifugal circuits contain a flow probe that displays how much blood is being returned to the patient. Servoregulation occurs by the same method as with roller pumps, in that venous and arterial pressure limits and goals are set and the pump (or the specialist) adjusts the revolutions per minute of the pump head or the desired flow to maintain set goals. Centrifugal pumps are easy to set up and have many potential benefits, but they are very sensitive to preload and afterload.[48] Understanding physiology to optimize centrifugal pump–driven ECMO is mandatory. Although the majority of centers have changed to centrifugal/hollow fiber ECMO systems, there is no evidence that they are superior to older roller-pump systems. A few reports note increased survival and need for fewer blood products with new systems.[49] Other reports have noted an increase in hemolysis and renal failure in patients receiving centrifugal pump ECMO, although this study included older devices.[50] Centrifugal pump/hollow fiber systems have allowed miniaturization of ECMO, which allows for easier patient transport and less exposure to blood products for priming, making patients more mobile with fewer safety concerns. Circuit tubing and components have a variety of surface coatings to

minimize the inflammatory response that occurs when blood contacts a foreign surface, although none have eliminated need for anticoagulation during ECMO support.

Advances in ECLS will likely be drawn from continuing work with artificial heart or ventricular support devices. The advent of percutaneous mechanical support devices other than ECMO allows for newer forms of support for patients with cardiac failure. Investigation into both short- and long-term ventricular assist devices for infants and children is ongoing, and several devices now exist that are applicable to children (the Berlin Heart is the most common).[51]

Membrane Lung

Until recently, the predominant membrane oxygenator was a silicone membrane envelope (with a plastic spacer screen inside) wound in a spiral fashion around a polycarbonate spool.[5,52] Gas flows within the interior of the envelope, and blood flows between the turns in the membrane envelope. Blood flow to the membrane lung is controlled by the pump setting. It is extremely efficient in gas exchange, but the high resistance to blood flow and the development of clots within the device have led to a reference for newer versions of the membrane lung.

Hollow-Fiber Oxygenator

Almost overnight, new hollow-fiber membranes have almost completely replaced the silicone lung during ECMO use.[33] Early versions of these oxygenators were plagued by difficulties with plasma leakage that resulted in very short life spans for the oxygenator and limited their use. The development of polymethylpentane membranes, which are extremely resistant to plasma leakage and have excellent gas exchange characteristics, make them the preferred device. These devices have a low resistance to blood flow and a lower priming volume than the traditional silicone membrane lung, which makes them faster and easier to prime. Newer versions maintain excellent gas exchange, have little hemolysis, and have durability for days to weeks without failure. In the United States, the Quadrox D device (Maquet INC) and the Medos oxygenators are currently available. Other countries use similar devices. An evaluation of pumps and oxygenators in more than 500 patients from 2012 to 2014 revealed that centrifugal pumps were used in 67% of patients and polymethylpentane devices in nearly 100%.[33]

Patient Populations Treated With Extracorporeal Life Support

The demographics of patients who have received ECMO support are shown in Table 59.1.[12,56]

TABLE 59.1

Overall Extracorporeal Membrane Oxygenation Results

	Total	Surv Extracorporeal Life Support	Surv to DC

Neonatal					
Respiratory	27,728	23,358	84%	20,592	74%

Neonatal Cardiopulmonary Failure

The majority of ECMO patients reported to the ELSO registry are neonates with respiratory failure.[57-60] The advent of inhaled nitric oxide, surfactant, high-frequency ventilation, and improved pre- and postnatal care has decreased the frequency of ECMO use in these small patients. Nonetheless, an average of 800 infants receive ECMO each year. Although neonatal respiratory distress syndrome has virtually disappeared, patients with meconium aspiration syndrome, persistent pulmonary artery hypertension of the newborn (PPHN), and sepsis still require ECMO support. These infants experience a combination of pulmonary parenchymal and vascular dysfunction that impairs gas exchange. The diagnosis, outcome, and mode of ECMO applied in neonatal patients are shown in Table 59.2.

TABLE 59.2

Common Diagnoses and Outcomes for Extracorporeal Membrane Oxygenation Patients

ECMO provides adequate gas exchange and circulatory support without further exposure to high oxygen concentrations or high airway pressures, thus fostering healing of the damaged lungs. The circulatory changes that result from the initiation of ECMO also lower pulmonary vascular resistance. Draining right atrial blood reduces right atrial pressure and promotes closure of the foramen ovale. In addition, the reduced blood flow to the pulmonary vascular bed decreases pulmonary flow, reduces pulmonary artery pressure, and relieves right-to-left shunting through the patent ductus arteriosus. Well-oxygenated blood flowing left to right through the patent ductus arteriosus promotes its closure. By relieving hypoxia, hypercapnia, and acidosis, ECMO promotes relaxation of pulmonary vascular tone. The amount and extent of pulmonary arteriolar smooth muscle begin to regress. These changes allow the transition to a mature circulation. The infant continues to receive ECMO until parenchymal lung disease heals sufficiently to allow adequate gas exchange or fetal pulmonary artery flow converts to a mature state and adequate gas exchange occurs. However, pulmonary function tests indicate that commonly infants are weaned from ECMO with only moderate improvement in mechanical lung function. These observations support the impression that circulatory abnormalities contribute importantly to neonatal "respiratory" failure and may partially explain the difference in outcome between neonates and older patients treated with ECMO. Historically, neonates have had the best survival of all ECMO groups (>70%). As more complex patients with multiple organ failure have received ECMO, overall survival in neonates has shown some decline.

Infants with congenital diaphragmatic hernia constitute a special subgroup of patients treated with ECMO for severe pulmonary hypertension and respiratory failure. Severe pulmonary hypertension or lung hypoplasia leads to about 50% mortality even with ECMO support. Morphologic examination, better understanding of the pathophysiology of this lesion, and stabilization with ECMO as needed preoperatively or perioperatively have improved the survival rate in some centers in this challenging group of patients.

Pediatric and Adult Patients

Approximately 400 non-neonatal pediatric patients undergo ECMO each year for severe respiratory failure, with an overall survival rate of 53% (see Table 59.2). Most of these patients have severe hypoxia, hypercapnia, or intractable air leaks. Pulmonary dysfunction resulting from bacterial or viral pneumonia, aspiration syndromes, intrapulmonary hemorrhage, acute respiratory distress syndrome, and less well-defined disorders have also been treated successfully with ECMO.[61,62] The uncertainties accompanying the use of ECMO in neonates, who compose a homogeneous group relative to other age groups, are compounded in older children. The enormously heterogeneous older pediatric population spans nearly two decades of physiologic development, and cardiorespiratory failure develops as a result of a multitude of different disorders. Furthermore, many patients have varying degrees of multiple organ failure along with respiratory disease at the time ECMO is instituted. Both lung disease and secondary organ dysfunction must be resolved to achieve survival. These factors result in lower survival rates in older patients treated

with ECMO than that achieved with the neonatal patient population.

One small subgroup of ECLS patients with excellent survival is made up of those with status asthmaticus.[59] One study of 64 asthmatic patients supported by ECLS noted the mean duration of ECMO was 94 hours, and 94% of the patients survived. Venovenous support was the cannulation mode in 86% of patients.[63]

One common theme in pediatric ECMO is the increasing complexity of patients. The multiple exclusion criteria used in the early days of ECMO have now been essentially eliminated, and each potential patient is generally considered on a case-by-case basis. Even patients with known bleeding disorders such as hemophilia have successfully received ECMO support.[64]

A review of the International Extracorporeal Life Support Registry (ELSO) found that patients with comorbidities prior to ECMO increased from 18% to 47% between 1993 and 2007 (Fig. 59.4).[65] Although such patients had decreased survival as compared to patients without comorbidities, overall 40% to 50% survived to hospital discharge. Patients with pertussis and fungal pneumonia continue to show increased mortality when compared to other groups. The willingness of clinicians to apply ECMO to groups previously excluded is highlighted by the numbers of patients with trauma who receive ECMO support.[62] More than 550 patients with respiratory failure and trauma are reported with survival of 50%. Patients with underlying malignancy also form an increasingly large percentage of ECMO support, rising from 0.3% to 1% of pediatric ECMO cases in the most recent review. Of 171 patients analyzed from 2008 to 2012, 55% survived their ECLS run and 48% survived to hospital discharge. A questionnaire sent to 118 ECMO centers noted that 95% of responding sites would consider the use of ECMO in a patient with malignancy. This response demonstrates the change in attitude among many clinicians with regard to patients with cancer.[19,66]

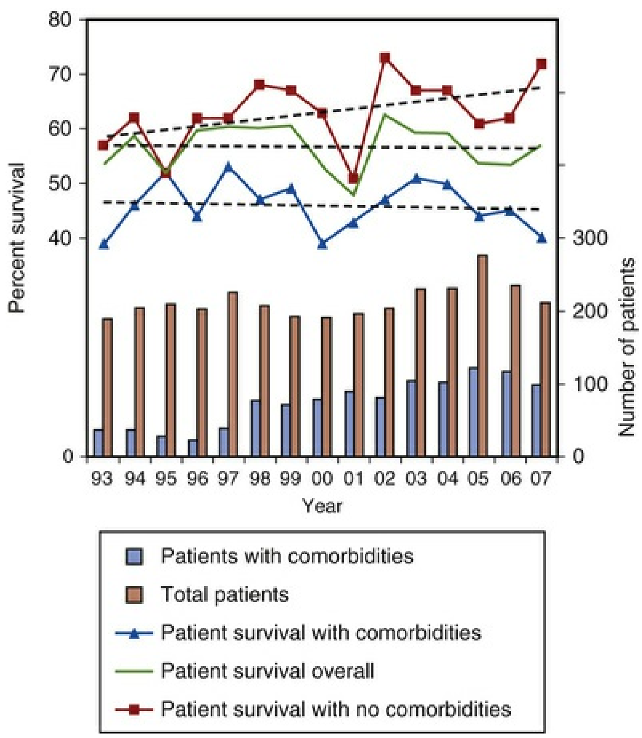

FIG. 59.4 Changes in pediatric ECMO for respiratory failure and outcome.

Dashed lines depict linear trend. (Reproduced from Zabrocki L, Brogan T, Statler K, et al. Extracorporeal membrane oxygenation for pediatric respiratory failure: survival and predictors of mortality. Crit Care Med. 2011;39:364-370.)

One group that remains the most difficult is made up of patients with underlying bone marrow transplant. Although ECLS has been applied to such children, usually for refractory respiratory failure, none have been reported as survivors to discharge in the ELSO registry. Anecdotal reports, however, of sporadic survival, combined with pleas from oncologists that the rapid rise of stem cell transplants and today's conditioning and posttransplant regimens are less toxic and lead to rapid engraftment, make this a controversial area that is still being explored. Selected patients are still receiving ECLS on a case-by-case basis. Anecdotal reports have noted that patients with newly discovered malignancy have also received successful induction therapy while on ECMO support.[68,69]

Although it is desirable to initiate ECMO prior to the onset of multiple organ system failure, many patients present with established organ failure. ECMO may provide an optimal environment for organ recovery in such patients, not just providing respiratory or cardiac support. Further, the ability to add adjunctive devices such as hemofiltration or dialysis (Fig. 59.5) to augment renal function and allow use of plasmapheresis, plasma exchange, or hepatic support devices is another aspect of ECMO support that may facilitate patient care and organ recovery.[70] Implementation of ECMO during multiple organ systems failure now occurs under a variety of conditions, with resolution of organ dysfunction and often with good outcome. Furthermore, because it avoids the circulatory derangements that often result from extreme forms of mechanical ventilation and provides systemic perfusion without the need for high-dose levels of inotropic agents, ECMO also may prevent damage to other systems.[62]

Extracorporeal Membrane Oxygenation in Adults

The most rapid rise in the use of ECMO is in adult patients. Since 2009, ECMO use

has increased over 400% in this population, with overall survival similar to that of pediatric patients (Table 59.3).[72-74] Early randomized trials of ECMO use in adults that did not show benefit have been criticized for poor study design and had complication rates in both control and ECLS groups that are much higher than those noted today. The randomized trial of venovenous ECMO compared with conventional mechanical ventilation in adults with respiratory failure in the United Kingdom (the Conventional Ventilation or ECMO for Severe Adult Respiratory Failure [CESAR] study) found a benefit to patients referred to a single ECMO center when outcome was examined at 6 months after discharge. A total of 180 patients were enrolled and randomly allocated to receive treatment (n = 90) at the single ECMO center in the United Kingdom or to receive conventional management ventilation (CMV) (n = 90) at a designated CMV center. Randomization criteria included a Murray score of >3 or severe respiratory acidosis with pH <7.20. Study results noted that 63% of patients allocated to "consideration for treatment by ECMO" survived to 6 months without disability compared with 47% of those allocated to conventional management (P = .03; risk ratio, 0.69; 95% confidence interval 0.05 to 0.97). Of note, 17 of 90 patients randomly assigned to "consideration for treatment by ECMO" who were treated within the ECMO center with a "gentle ventilation" (low tidal volume, limited pressure) strategy were not treated with ECMO and 14 survived.[75] Whether this finding represents the beneficial effects of increased expertise within centers that support patients with severe respiratory failure with ECMO availability or other factors is unknown. Early transfer of patients with potentially reversible respiratory failure who meet similar criteria to those in the CESAR study may be recommended. This study also found a cost-benefit ratio in terms of quality of life and economics that was favorable in the ECMO group. As with most randomized studies, critics questioned some aspects of the CESAR study design, most notably that there was no mandated protocol for ventilator management in the CMV arm, and this has led to another randomized trial of ECMO versus CMV in Europe, which is ongoing.

TABLE 59.3

Proposal for and Relevance of Long-Term Follow-Up After (Neonatal) Extracorporeal Membrane Oxygenation Treatment

	Specific Topics	Relevance/Intervention
Infancy	Growth Hearing assessment Screening CKD Neurologic impairment Mental and motor development	Hyperalimentation Early referral audiology Early recognition and treatment Early recognition, rehabilitation Referral physical therapist
Toddler	Growth (mainly in CDH) Screening CKD Neurologic impairment Language development Motor function development	Hyperalimentation Early recognition and treatment Rehabilitation Hearing assessment, speech-language pathologist Referral physical therapist
School age	Lung function assessment Exercise capacity Growth (mainly in CDH) Screening CKD Motor function development Neuropsychologic assessment Self-esteem	Evaluate reversibility of airflow obstruction Exercise training, sports participation Hyperalimentation Early recognition and treatment Referral physical therapist Hearing assessment, early school support Early intervention, support

As with pediatric patients, use of ECMO in adults with trauma (even with recent head injury and intracranial hemorrhage), sepsis, HIV, and other disease processes that may have been excluded from ECMO consideration in the past is on the rise.

One special patient population is those patients awaiting lung transplant. With the advent of new equipment and patient management techniques that allow patients to be awake, mobile, and undergo active rehabilitation while on ECMO support, this area represents a new growth region where excellent results are being reported in both pre- and posttransplant care. This is especially the case in adults with chronic obstructive pulmonary disease (COPD) or similar diseases who require carbon dioxide removal more than oxygenation support. Such gas exchange is extremely efficient even with venovenous cannulation and requires only a fraction of circulating blood volume to be lifesaving.[76-79]

The new, large, percutaneous cannulas for venovenous ECMO support, along with small centrifugal pumps and less cumbersome total ECMO systems, are all advantageous to the adult population. Alternative support techniques such as pumpless extracorporeal support and the implantable artificial lung are additional clinical modalities for adult respiratory failure.[80]

Extracorporeal Membrane Oxygenation for Myocardial Dysfunction

The International ELSO Registry lists more than 9000 patients who have received ECMO for cardiac failure, predominantly following surgical repair of congenital heart defects (Table 59.4). Outcome of neonatal and pediatric patients notes that 60% are successfully weaned from ECMO and 43% survive to be discharged from the hospital. Adult cardiac patients have slightly worse survival rates, with 48% weaned off ECMO and 34% discharged from the hospital.[81-85]

TABLE 59.4

Cardiac Extracorporeal Membrane Oxygenation Patients and Outcome (Under Age 16 Years)

Although center-specific factors separating patients with myocardial dysfunction who will not survive from those who will recover adequate function without such

invasive support have been put forth in the literature, none have proved to be universally accepted. Patients with evidence of low cardiac output and shock (including low urine output, poor perfusion, hypotension, elevated cardiac filling pressures, and low mixed venous oxygen saturation) despite maximal respiratory and pharmacologic support are candidates for ECMO rescue. The absence of clear criteria for using ECMO and the reluctance to initiate such invasive support often delay use until cardiac arrest has occurred. As a result, a significant number of patients treated with ECMO have recovered myocardial function only to die of hypoxic/ischemic encephalopathy that was experienced before ECMO was initiated. Such events have now led to a trend in cardiac patients to consider ECMO earlier in the course of dysfunction. Availability of ECMO is now a recommended part of pediatric cardiac surgical programs. As newer and smaller cardiac assist devices are developed for pediatric patients, the need for ECMO support in this population may wane, but at this time ECMO provides the most readily available support technique over a wide range of patient ages and sizes for cardiac failure.

Most patients requiring ECMO for circulatory support have undergone venoarterial ECMO because of its capacity to provide both respiratory and circulatory support. The majority of survivors recover myocardial function within 72 hours of ECMO support, although patients with myocarditis or cardiomyopathy can have good survival rates even after prolonged ECMO support. In most reports, patients whose myocardial function has not improved substantially within 24 to 72 hours of rest on ECMO are not likely to recover cardiac function sufficient to support life. Transplantation may be an option in these patients if their underlying cardiac anatomy and general clinical condition make them appropriate candidates. Patients who fail to improve often are evaluated by cardiac catheterization early during ECMO to identify residual lesions (if postoperative) or abnormalities that may be amenable to further surgical repair or catheterization laboratory interventions. Cardiac patients with good respiratory function may not routinely require ventilator support. Such patients may require only low levels of ventilator support or can be extubated during ECMO, which may alleviate the need for heavy sedation to maintain endotracheal tube position.

Myocarditis and cardiomyopathy are two categories of nonsurgical cardiac failure that have increasingly received ECLS support.[83] Although it may be difficult acutely to differentiate unknown cardiomyopathy from viral myocarditis, both diseases may benefit from mechanical support with ECMO or ventricular assist devices that create a stable hemodynamic milieu where the heart can “rest” and recover. One review of the ELSO registry noted a 61% survival rate in 255 children with myocarditis. Seven patients received cardiac transplantation, with six surviving to discharge. The average duration of ECLS in nontransplant patients was 168 hours, with a range of 145 to 226 hours. Multivariate analysis showed that female gender, arrhythmia while undergoing ECMO, and renal failure requiring dialysis were associated with increased in-hospital mortality.

One analysis of a single institution's experience of ECLS following cardiac surgery in children spanning a 17-year period found that 38% of cardiac patients survived to discharge. One-third of the children had single ventricle cardiac pathology. Cannulation occurred in the operating room in 46% of patients, and 51% of cannulations took place in the ICU. Complications included reexploration for bleeding (56%), neurologic complications such as ischemic brain injury or

intracranial hemorrhage (17%), renal dysfunction (10%), and pulmonary hemorrhage (5%). Factors associated with mortality were renal failure, neurologic complications, longer ECLS duration, and need for recurrent ECMO support. Mortality also may have been affected by the lack of a cardiac transplant program for patients not recovering myocardial function.[84]

In another review of 58 patients receiving ECMO following congenital heart defect repair (January 2003 through June 2008), 67% of patients were weaned off ECMO support and 41% survived to hospital discharge. Single ventricle repair was noted in 53% of patients. When analyzed for factors associated with outcome, ECMO duration longer than 10 days (OR, 6.1), urine output less than 2 mL/kg/h in the first 24 hours (OR, 15), renal failure (OR, 9.4), and pH less than 7.35 after 24 hours of ECMO (OR, 82.3) were all found to be independent predictors of failure to wean from ECMO. Independent predictors of failure of hospital discharge in spite of successful decannulation were ECMO time of 10 or more days (OR, 11.5), a red blood cell transfusion volume greater than 1000 mL/kg during the entire period of ECMO course (OR, 11.5), and sepsis. Patients who underwent single ventricle repair were at higher risk of hospital mortality (OR, 4.9). This study also developed a probability of weaning from ECMO table based on the four previously mentioned predictors. For example, a patient with an ECMO duration of more than 10 days who had renal failure and poor urine output and pH at 24 hours of ECMO would have a predicted mortality rate of 100%. Similar evaluations in larger series of patients to validate such assessments should be performed to refine ECMO care and improve family counseling regarding prognosis.[85]

To obtain more detailed information on cardiac surgical patients who receive ECLS, an addendum to the general ELSO registry data form was developed and should provide more details on these patients. Although ECMO remains the most common method for support of patients with cardiac failure, new and miniaturized mechanical support devices such as the Berlin Heart and other ventricular assist devices offer alternatives with potential advantages to infants and children.

Extracorporeal Membrane Oxygenation for Resuscitation

Another growing area of the use of ECLS is in support of patients with refractory cardiac arrest.[86-90] This type of support is termed *extracorporeal cardiopulmonary resuscitation (ECPR)*, or ECMO during cardiac arrest. Designed as a resuscitative tool for patients in cardiac arrest, ECPR has been reported in more than 5000 neonates, children, and adults, with an overall survival-to-discharge rate of 35% to 40%. To facilitate expedient access to ECMO support for ECPR, in situations of acute deterioration or whenever there is insufficient time or personnel for routine ECMO, many centers maintain an ECMO circuit setup that is preprimed with a crystalloid solution and stored (usually up to 30 days). Other centers use a portable, centrifugal bypass perfusion system that also is easily set up within 10 to 20 minutes. Both methods often use a hollow-fiber membrane lung.[85-90]

In one meta-analysis of ECPR, 288 patients were identified, with 40% surviving to hospital discharge. Venoarterial ECMO was used in 99% of patients, and 63% underwent cannulation through an open chest. The median length of stay on ECMO was 4.3 days. The overall occurrence of complications was high (59%). The most

commonly occurring complications were neurologic (27%), renal (25%), sepsis (17%), bleeding (7%), and multisystem organ failure (9%).

In an analysis of children with cardiac arrest, use of ECMO was noted as one factor associated with improved survival. Another review from the National Registry of CPR found 199 pediatric patients who were treated with ECMO during arrest with an overall survival rate of 44%. In 59 survivors whose neurologic outcome was recorded, 95% had favorable outcomes based on Pediatric Cerebral Performance Scores. By multivariate analysis, renal insufficiency, metabolic or electrolyte abnormality at the time of arrest, and use of sodium bicarbonate or tromethamine were associated with decreased rates of survival. Underlying cardiac illness was associated with an increased rate of survival to discharge.[87]

One cautionary note is that cardiac patients are often reported to have improved outcomes when compared with noncardiac patients. Whether this finding represents disparity in access to ECPR between cardiac and noncardiac patients, underlying pathophysiology or other factors require ongoing study. An addendum to the ELSO registry that has been specifically designed for patients experiencing cardiac arrest may provide more detailed information to answer ongoing questions.

Of interest, several adult reports have found that percutaneous femoral artery and vein cannulation during arrest are efficient and associated with good outcomes.[91,92] The SAVE JAPAN study noted increased survival with such an approach applied in the emergency department to adults patients with out-of-hospital arrest.[93] A review from Australia (the CHEER trial) also found that cannulation of the femoral vessels by critical care physicians, combined with induced hypothermia via a 30 cc/kg bolus of iced saline, in selected patients with in-hospital or out-of-hospital arrest had an overall survival of 54% with good neurologic outcome. Time to establish ECMO once the ECPR team arrived was 20 minutes, and overall CPR duration prior to ECMO initiation averaged 56 minutes.[94] It is likely that similar efforts may expand to children now that cannulation strategies and equipment have become available.

Although ECPR initiation has become routine in many centers, decision making as to when to *not* offer or to discontinue ECMO efforts if recovery seems futile has opened a new area of ethical discussion. The reluctance of family members to agree with discontinuation of support highlights a dilemma that some clinicians have been faced with. Setting firm goals and decision-making processes, which are explained to the family during the consent process or immediately after initiation in terms of emergent ECLS, may alleviate some of these situations.[95]

Trauma Patients

Trauma patients, particularly those with multiple injuries, are at risk of respiratory failure. Trauma remains the leading cause of death in young adults. Common pathophysiologic mechanisms include direct chest injury causing pulmonary contusion, long bone or pelvic fractures causing fat embolization, or an inflammatory-mediated event following systemic injury known as acute respiratory distress syndrome. Extracorporeal membrane oxygenation provides *lung rest* by permitting reduced ventilator settings and limiting further barotrauma while maintaining tissue perfusion and oxygenation. In a study comprising 28 adult patients treated with ECMO because of trauma-related respiratory failure, 20 patients were successfully weaned off ECMO and discharged. Eight patients died as

a result of overwhelming sepsis and irreversible cardiogenic shock. Good outcomes in pediatric patients undergoing ECMO following trauma also have been reported.[62,96]

Other applications of ECMO include management of patients with extreme hypothermia who require gradual extracorporeal rewarming. Trauma patients with massive hemorrhage and ongoing coagulopathy from transfusion-related hypothermia also have received short-term extracorporeal support with bypass to facilitate rewarming to temperatures that help normalize the coagulation process. Once rewarming is achieved, cannulas are withdrawn.

Other Extracorporeal Support

Other advances in membrane lung development have allowed adequate oxygenation without an extracorporeal pump.[97] One device, the Novalung, takes arterial blood from the femoral artery and directs it through a hollow-fiber device for oxygenation and carbon dioxide removal, and then reinfused blood is directed into the femoral vein. Experience with this device is growing, and multiple reports of bridging to lung transplantation or to resolution of lung injury can be found in the literature. Other devices that are effective in removing carbon dioxide with low blood flows are also becoming available.[92-94]

Patient Selection Criteria

Various mortality prediction criteria have been put forth as indicators of when ECMO rescue is best applied. Many of these criteria have been derived from small series of historical data for patients with respiratory failure or were extrapolated from neonatal respiratory failure data. Attempts to provide universally accepted criteria for institution of ECMO have proved difficult.[98-102]

The current state is that almost every patient who receives ECLS is selected on a case-by-case basis. The clinical team discusses the risks and benefits of ECLS in light of the current ICU status and makes a decision about whether or not to offer ECMO to the family as an option. Given the complexity of patients receiving ECLS and the comorbidities often present, clinicians from other services outside the ICU staff (pulmonary, oncology, neurology, etc.) are beneficial in this discussion. Many centers also have smaller teams with special expertise or interest in ECLS within the overall ICU faculty who provide advice on candidacy, ECLS strategy, and patient management.

For the majority of patients who undergo ECMO, less invasive methods of respiratory support have failed. Such methods of support often include conventional mechanical ventilation in pressure control or pressure-regulated volume control modes, high positive end-expiratory pressure (PEEP), high-frequency ventilation (HFV), surfactant, or iNO.[103] One report examined the current utility of respiratory severity indices used in the past for potential ECMO eligibility in 118 children with acute hypoxemic respiratory failure. Indices examined included the $AaDO_2$, OI, PaO_2/FiO_2, ventilation index, and mean airway pressure (Paw), as well as individual ventilator settings and arterial blood gas values. When risk of mortality based on respiratory severity indices predictions were compared with actual mortality

observed in these 118 children, survival was much better than would have been predicted based on historical data.[100] As an example, an OI greater than 40 has been associated with more than 80% risk of death in the past. Although only 15 patients reached an OI greater than 40 in this study, the positive predictive risk of mortality in these patients was 40%, significantly lower than predicted by past reports. An $AaDO_2$ greater than 450 for 24 hours, a Paw higher than 23, or an $AaDO_2$ higher than 420 had positive predictive value for mortality rate of 32% to 40%. Using logistic regression, no respiratory parameter ($AaDO_2$, OI, Paw, ventilator settings, or blood gas values) was independently correlated with death. All deaths were associated with multiorgan system failure, coincident pathology, or perceived treatment futility, leading to limitation or withdrawal of care. The overall mortality rate of these 118 children was 22%, with no previously healthy child dying from respiratory failure. Nonconventional therapies applied included HFV in 25 (21%) of 119 (64% survival), surfactant administration in 15 (13%) of 119 (73% survival), iNO in 38 (32%) of 119 (69% survival), and ECMO in 4 (3%) of 119 (75% survival) of patients.[100]

Although severity scores such as PaO_2/FiO_2, shunt fraction, compliance, and others have been used to identify potential ECMO candidates, in children the oxygenation index has remained in favor, as it combines the level of ventilatory support being given and the oxygen level obtained in arterial blood. This measure is calculated as follows:

$$OI = \frac{\text{Mean Airway Pressure (cm } H_2O) \times FiO_2}{PaO_2 \text{ (torr)}}$$

Scores >40 or from 30 to 40 without improvement have been associated with high mortality in the past and were used as ECMO candidacy alerts. Data, however, have noted doubling of mortality from <20% to >40% when OI exceeds 16. When combined with another variable of lung injury, pulmonary dead space, OIs of >16 with dead space of >23% resulted in an observed mortality risk of 60%. In an evaluation of 65 children with serial OI measurements obtained from the electronic medical record from a single center, mortality tripled when the OI exceeded 17. In another review of factors associated with death in children with severe respiratory failure, the peak oxygenation index and pediatric risk of mortality (PRISM) score were found to be independent predictors of outcome, although no definitive OI cutoff that predicted death could be identified. These findings, along with the increased ease of applying ECMO, have led to discussion as to whether ECMO should be applied at OI severity scores much lower than in times past. Indeed, in the adult population, there is now discussion as to whether implementation of ECMO to avert intubation or shortly after the need for mechanical ventilation should be performed.

In an attempt to provide standard definitions for respiratory failure in children and develop consensus regarding pediatric respiratory care guidelines, an expert panel of 19 international clinicians met and examined thousands of published reports by the Rand/University of California at Los Angeles (UCLA) method and achieved consensus results using the modified Delphi method. ECLS was one of the nine areas selected for recommendations. As there were few high-quality report

scores for ECMO as scored by the Rand/UCLA method, recommendations were developed primarily by consensus expert opinion. These included the following: (1) serial measurements of severity of illness as criteria for ECMO should be used rather than a single cutoff value; (2) cases should be discussed among treating clinicians as a team; (3) ECMO should not be offered to patients in whom life-sustaining measures were restricted; (4) quality of life and long-term outcome from comorbidities should also be evaluated; (5) all centers should report patients and outcome to a registry, such as ELSO; (6) benchmarking of centers against overall data from such registries is useful to improve quality care.

This consensus report represents baseline agreement on respiratory definitions and care, and it is likely that further refinement of recommendations will occur over time.

Physiology of Extracorporeal Life Support: Gas Exchange and Oxygen Delivery

Oxygenation

The difference between the PO_2 in the gas supplied to the oxygenator and that in the patient's systemic venous blood provides the driving pressure across the membrane lung. As an example, 30% of oxygen blended into the gas entering the oxygenator will result in an estimated PAO_2 of about 228 torr at sea level. The PO_2 of venous blood entering the oxygenator depends on the difference between oxygen delivery and consumption in the patient, but it is usually about 40 torr. The driving pressure for oxygen diffusion into the blood thus would be approximately 188 torr (228 torr – 40 torr = 188 torr), which is adequate to achieve 100% saturation of hemoglobin. Higher oxygen concentrations in the gas phase may be necessary to compensate for loss of membrane surface area over time to maintain hemoglobin saturation. Faster flows through the oxygenator may also decrease the time for gas exchange to occur. At postoxygenator oxygen saturations greater than 95%, increasing the oxygen concentration of the sweep gas has little incremental effect on blood oxygen content. For this reason, oxygen concentration in sweep gas usually is adjusted to maintain an oxygen saturation of approximately 95% in postoxygenator blood.

Carbon Dioxide Exchange

Even though the pressure gradient for carbon dioxide between venous blood and membrane gas is less than that for oxygen, carbon dioxide removal is excellent across the membrane lung. Despite the small pressure difference, the membrane's high diffusion coefficient for carbon dioxide allows excellent carbon dioxide removal, even at low flow rates. To eliminate more carbon dioxide, the gas flow in the membrane must be increased, much as alveolar ventilation must increase to eliminate carbon dioxide from the body under physiologic conditions. Carbon dioxide removal is also limited by the surface area across which gas exchange can occur. Thus increased carbon dioxide clearance may be obtained by using larger oxygenators or using more than one oxygenator in parallel in the circuit. Conversely, to prevent excessive CO_2 removal and hypocapnia in small infants and neonates, the

sweep of gas through the membrane lung can be reduced or low levels of carbon dioxide may be blended into the gas mixture to further reduce the partial pressure difference between blood and gas and maintain normocarbia.

Oxygen Delivery

During venoarterial ECMO, both increasing oxygen delivery and increasing the patient's PaO_2 and arterial saturation can be accomplished by increasing the ECMO flow rate. This strategy diverts more of the systemic venous return into the ECMO circuit for oxygenation while at the same time proportionally decreasing the amount of venous blood that enters the diseased pulmonary circuit. Studies have suggested that complete bypass of the pulmonary circuit may lead to pulmonary alkalosis or ischemia and cause direct damage of the pulmonary capillary bed. Microsphere studies have shown that most coronary artery perfusion during venoarterial ECMO comes from native left heart ejection, which is another reason why ECMO is performed in a *partial* bypass state.[104,105] The result of increasing ECMO flow will be an increase in oxygen delivery provided by the circuit and an elevation in measured systemic arterial saturation and PaO_2. Another means to change the proportion of native blood flow to that from the ECMO circuit is to decrease the overall blood volume in the patient. During cardiopulmonary bypass, filling pressures and overall blood volume can be adjusted by removal of blood volume into the bypass circuit. Circulating volume is also frequently decreased by modified ultrafiltration. During ECMO, these same principles can be followed: Excessively high filling pressures can be lowered by simply removing blood volume from the circuit, and diuretics and renal replacement strategies can be used to control fluid balance. Care must be taken, however, to avoid decreasing circulating volume excessively, because this may in turn cause tissue hypoperfusion or an increase in oxygen extraction.

Cardiac output can be altered during ECMO by increasing or decreasing the amount of blood diverted from the patient to the ECMO circuit. As blood returning from the ECMO circuit is already highly saturated with oxygen, oxygen content can be augmented primarily by increasing hemoglobin levels in the patient. Oxygen delivery supplied by the ECMO circuit can be calculated by pump flow as the surrogate for cardiac output and oxygen content by hemoglobin and postmembrane lung oxygen saturation. Determining the amount of oxygen delivery supplied by the native heart is less clearly calculated. Monitoring of adequate oxygen delivery is aided by following venous saturation. Low venous saturation and other markers such as elevated lactate, poor perfusion, decreased urine output, and mental status changes may indicate the need for improved oxygen delivery. If ECMO flow cannot be increased to provide adequate support, an additional drainage cannula to augment ECMO flow and allow increased support may be needed.

In patients who undergo cannulation via the venovenous route, reduced systemic oxygenation will be observed compared with patients with venoarterial ECMO. This reduced systemic oxygenation is a result of the lower amount of native cardiac output that can be delivered to the circuit, as less native blood can be drained with venovenous cannulation. Several features unique to venovenous cannulation are important to understand. First, because blood is both withdrawn and reinfused into the venous circulation, adequate native cardiac function must exist to provide the “pumping” of oxygenated ECMO return to the patient's systemic circulation. One

factor that may influence cardiac function during venovenous ECMO is that well-oxygenated blood returning from the ECMO circuit will enter the right heart. This highly oxygenated blood may reduce pulmonary artery pressure by reducing pulmonary vascular resistance, which may in turn improve right heart function. Likewise, highly saturated blood returning to the left ventricle and pumped to the coronary arteries may improve myocardial blood flow and improve cardiac performance. For these reasons, some clinicians will initiate venovenous ECMO even in patients with cardiac dysfunction and transition to venoarterial ECMO if support is inadequate. Other clinicians prefer to use venoarterial ECMO preferentially if cardiac dysfunction exists. Of note, 30% of children with vasoactive requirements prior to ECMO tolerated venovenous ECMO well in one report.[20]

Another feature of venovenous ECMO is that because blood is withdrawn and reinfused into the venous side of the circulation, some portion of oxygenated blood is likely to be lost into the venous drainage cannula prior to entering the systemic arterial circulation.[33] This phenomenon is known as *recirculation,* and it can be a major limiting factor in providing adequate patient support with venovenous ECMO. With double-lumen cannulas placed via the right IJ vein to the right atrium, careful orientation of the inflow lumen toward the tricuspid valve may limit recirculation. The larger separation of drainage and inflow lumens with the Avalon device seems to be associated with fewer recirculation difficulties than occurs with prior double-lumen cannulas (Fig. 59.6).

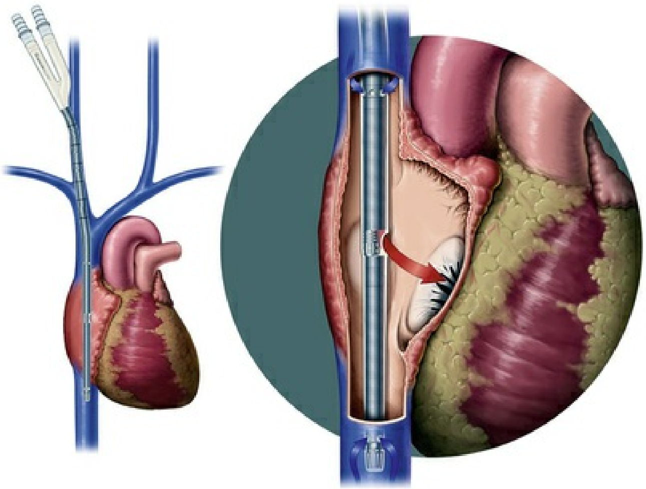

FIG. 59.6 Avalon cannula. (Reproduced from Maquet, Inc., with permission.)

With two-site venous cannulation, recirculation can be limited to some degree by ensuring that some distance separates the end tips of the drainage and infusion cannulas in the body. Recirculation also can be reduced by draining from the femoral vein cannula and reinfusing into the right IJ vein cannula. The extent of recirculation can be estimated by following the venous saturation in the ECLS circuit; high levels of recirculation will elevate the displayed venous saturation on the drainage line because some of the highly saturated return from the ECLS circuit is immediately drawn out by the drainage cannula. Following adequacy of oxygen delivery in the patient by means of hemodynamic stability, measures of acid-base balance (lactate) and clinical measures of adequate perfusion and oxygenation are

required. Whether venovenous cannulation will provide adequate capture of the patient's cardiac output for ECMO support depends on how large the cannulas are, where they lie in the vessel, and how much overall ECMO support the patient requires.

New venovenous cannulas and placement strategies may limit recirculation, but it is unlikely that it can be prevented totally. Persistent signs of inadequate oxygen delivery or continued hemodynamic instability with venovenous ECMO may require conversion to venoarterial ECMO. One indication of recirculation is high measured venous saturations in the ECMO circuit because of mixing of well-oxygenated blood with systemic venous return. Unlike venoarterial ECMO, decreasing the flow rate of blood in this circumstance may decrease the amount of recirculation that is being observed and improve oxygen delivery to the patient. Monitoring venous saturations from another site in the body may be helpful to monitor adequacy of support in this circumstance.

One novel means of improving oxygenation to the head and upper body in patients who have undergone venovenous cannulation through the bilateral femoral veins is to add an additional venous cannula via the right IJ vein to the right atrium. Connecting this cannula to the inflow return side of the ECMO circuit will increase the amount of oxygenated bypass directly returning to the right heart. This procedure may improve overall oxygen delivery to the patient while still avoiding the need for arterial vessel cannulation.

Loose occlusion of the roller heads against the raceway tubing also can lead to less blood being propelled forward through the ECMO circuit and reduce systemic oxygen delivery. In centrifugal pumps, low head revolutions also can result in inadequate forward flow of blood to the patient, and if the patient's arterial blood pressure is higher than that generated within the centrifugal circuit, arterial blood can flow from the patient into the centrifugal circuit. Some circuits contain a one-way valve in the circuit, which prevents backflow. Increasing the revolutions per minute in the pump head will reverse this problem. Persistent vasodilation, which occurs in patients with sepsis, may require the administration of low levels of vasoconstricting agents to maintain adequate central venous pressures and adequate pump return without massive fluid administration.

Patient Management

Infants who are candidates for ECMO should undergo cranial ultrasonography, if time allows, to identify existing intracranial hemorrhage (ICH) prior to ECMO initiation. Although ICH greater than that confined to the germinal matrix (grade I) has been a contraindication to ECMO in the past, concerns with expansion of existing lesions due to anticoagulation have lessened and successful ECMO with good neurologic outcome has occurred even with infants with larger ICH. Standard care is the performance of repetitive ultrasounds or computed tomography examinations if concerns of intracranial pathology exist and to monitor the extension of known lesions. In many patients, emergent initiation of ECMO precludes any imaging procedures, and clinical neurologic evaluation may be hampered by ongoing sedation or neuromuscular blockade. Older patients may receive computed tomography prior to ECMO if time and patient status allow.

The decision to treat a patient with ECMO is made on the best assessment of

neurologic function. Once hemodynamic and gas exchange have been stabilized with ECMO, more informative neurologic testing or examination can be performed. If the patient has evidence of neurologic devastation, then support can be withdrawn.

Echocardiography is usually performed prior to institution of ECMO in infants to determine if hypoxia is a result of structural defects in the heart, which may be better served by surgical repair than by ECMO support. Echocardiography also can identify ventricular dysfunction, pulmonary hypertension, and pericardial effusions; these data are useful to properly manage the patient and to select the optimal form of ECMO or elect less invasive procedures if warranted. ECHO also is used to detect the presence and direction of central shunts within the cardiac system.

Other useful pre-ECMO considerations are to determine where cannulation is optimal to ensure that those vessels are patent by ultrasound and to ensure that planned vascular access is not already in use with an indwelling venous or arterial line. Movement of indwelling catheters to an alternative site in this circumstance should be carried out prior to ECMO if time allows. In patients with a history of repetitive surgical procedures or central line insertions, evaluation of vessel patency at the bedside or from a review of the patient record can be helpful. Information on patients who are critically ill and in whom ECMO *should* or *should not* be considered is useful for the clinical team to include in handoffs. This can avoid confusion in an emergent situation. Consider informing the family if it is deemed that their child is *not* an ECMO candidate and discuss the rationale.[95]

Laboratory measures of blood and platelet counts, electrolyte levels, and coagulation are included in data collection as ECMO is being planned. Correction of existing coagulopathy by infusions of plasma, cryoprecipitate, or platelets may be helpful to prevent early bleeding and to correct baseline dysfunction.

Cannulation and Initiation of Extracorporeal Life Support

Cannulation is usually performed at the bedside, with the patient receiving a combination of local anesthetics and intravenous analgesics, sedatives, and neuromuscular blocking drugs. An initial bolus of heparin (usually 50 to 100 units per kg) and continued heparin infusion ensure systemic anticoagulation for the duration of ECMO. Activated clotting time, measured at the bedside, provides a gauge for adjusting the heparin dose to avoid either catastrophic clotting in the circuit or bleeding complications. The ECMO flow is initiated at 50 mL/kg/min and is increased in 50- to 100-mL increments. In infants, a rate of 100 to 200 mL/kg/min usually provides adequate perfusion and oxygenation, although patients in a state of high cardiac output, such as sepsis, may require a higher rate. Use of high-flow ECMO also is recommended in patients with single ventricle physiology and a systemic-to-pulmonary artery shunt to provide adequate circulation for both systemic and pulmonary organs. Pediatric patients usually require about 90 mL/kg/min of ECMO flow to maintain adequate oxygen delivery, and adult patients require rates of 50 to 70 mL/kg/min. Estimates of flow needs also can be predicted by using cardiac index data based on body surface area (BSA). One caution in estimating ECMO flow in this manner is that patients with sepsis or multiple organ dysfunctions may require flows that are much higher than predicted. These factors

must be taken into account when selecting cannula size, as larger cannulas than that predicted by BSA may be required. In venoarterial ECMO, the arterial waveform provides a rough estimation of the degree of bypass provided by the ECMO circuit. ECMO is provided in *partial* bypass form, as total bypass of the pulmonary circuit has been associated with pulmonary ischemia.[106,107] Because ECMO flow is nonpulsatile, increasing flow and decreasing left ventricular output will result in a flattening of the arterial wave contour and a narrowing of the pulse pressure. Severe myocardial dysfunction also may cause a flattened wave contour because left ventricular output may be minimal. This effect must be kept in mind when waveform contour is used to monitor the extent of bypass.

Priming

Priming of the ECMO circuit prior to initiation is accomplished with a crystalloid solution that is then replaced with blood. Because required blood usually has been citrated and stored, it may be acidotic, depleted of calcium, and have a high potassium level. Calcium (usually as calcium chloride), bicarbonate or tromethamine, and heparin are added during the priming procedure. Electrolytes should be measured in the priming blood before bypass is initiated, because disturbances of cardiac rhythm or frank cardiac arrest can occur upon initiation of ECMO. Hyperkalemia exists almost universally in the ECMO primed circuit despite buffering by calcium and bicarbonate. The potassium level rarely causes systemic effects once the ECMO prime is diluted with the patient's intrinsic blood volume. As an example, if a neonatal patient with a blood volume similar to that of the ECMO circuit has a potassium level of three and the ECMO prime has a potassium level of seven, the circulating potassium level may be around five upon ECMO initiation. This scenario is unlikely to cause systemic or cardiac effects. Larger patients having blood volumes much greater than that of the ECMO circuit will have less risk of hyperkalemia or hypocalcemia. Use of the freshest blood available also may lessen the degree of hyperkalemia in the primed circuit. Rarely, hyperkalemia may be of such concern that blood must be washed prior to ECMO use or filtered via a hemofiltration device in the ECMO circuit to reduce the potassium level. Newer centrifugal/hollow fiber systems have a priming volume much lower (<400 cc) than with older roller-pump/silicone lung configurations.

Patient Management During Extracorporeal Life Support

Hypovolemia causes low central venous pressures and results in decreased venous return to the circuit. This situation can be corrected easily with fluid administration. Oxygen delivery also can be raised by increasing the pump flow rate, which increases blood diverted into the ECMO circuit for oxygenation. Anemia can be corrected with transfusion of blood products.[108,109] Hemoglobin must be maintained to sustain adequate oxygen content. Clinicians disagree about the level of hemoglobin needed during ECMO, but the current trend to accept lower levels of hemoglobin in critically ill patients is also followed in ECMO patients, with most centers delaying routine transfusion until the hemoglobin is 10 g/dL or even lower if the patient seems to be doing well. The needs of the patient and the risks of transfusion are a balance that the clinical team assesses on an ongoing basis.

Whatever level of hemoglobin is chosen for “routine” patient management, an intermittent administration of packed red blood cells to maintain adequate blood volume and hematocrit will be required. Fresh frozen plasma also may be given intermittently to provide adequate clotting factors and help prevent excessive bleeding. Platelet sequestration in the ECMO circuit is a constant problem. Historically, platelet counts of 80,000 to 100,000/mm^3 have been maintained routinely for patients undergoing ECMO to deter bleeding, but multiple examples now exist of patients undergoing ECMO with thrombocytopenia of 30,000/mm^3 or lower and in whom massive bleeding was not a problem. Although patients often require frequent platelet transfusions, the capacity of transfusions to increase platelet counts to high levels may be limited in some patients, such as those with cancer. In these patients, lower platelet counts may be allowed and careful monitoring for bleeding is maintained.

Another problem with ECMO, especially for prolonged runs, is heparin-induced thrombocytopenia (HIT). HIT should be suspected in any patient receiving heparin when a drop in platelet count occurs that is unresponsive to platelet transfusion or when the platelet count continues to fall without an identified reason. Although HIT usually develops 5 to 15 days after the initial exposure to heparin, it can occur immediately in patients with previous exposure to heparin, such as patients who have undergone cardiac surgery. HIT associated with immune response to heparin can result in severe thrombocytopenia. The only “cure” is to stop the patient from being exposed to heparin. During ECMO, stopping exposure to heparin necessitates the use of other anticoagulation methods. Currently, lepirudin, biliverdin, and argatroban are alternatives that have been commented on with regard to ECMO, although these treatments are not widely used in the pediatric population in general.

Despite advances in technology, anticoagulation is needed to prevent clotting of the extracorporeal circuit. Heparin remains the mainstay for anticoagulation, but the optimal management scheme to prevent thrombosis without causing bleeding remains elusive. Although the activated clotting time (ACT) remains the most common method for monitoring heparin and anticoagulation, as an improved understanding of the coagulation cascade and the means to measure factors within it have occurred, other regimens now include the anti-Xa level, antithrombin, specific factor analyses, and thromboelastography. No algorithm has proved superior to another in terms of limiting complications or improving outcomes. It is important to understand the pros and cons of each test in terms of the blood volume required for testing, accuracy, and cost. As one example, the use of antithrombin, a protease inhibitor that inactivates factor Xa and thrombin and has markedly enhanced action in the presence of heparin, has increased 9.5-fold to use in over 52% of ECMO patients, despite no evidence it decreases complications or even identifies the correct dose in children. In a similar fashion, anti-Xa measurement, which gives a more direct assessment of heparin level than the whole-blood ACT test, is also used frequently. Although it is not shown to be superior to ACT, it can be monitored intermittently at intervals less than the usual every hour for ACT. Thromboelastography, a technique which produces a visual picture that gives information on the degree of anticoagulation induced by heparin and other information regarding coagulation and platelet defects, is also being used more as new technology makes it easier to perform. Hopefully continued research in this area will yield an optimal anticoagulation regimen that will reduce bleeding and

thrombotic complications.[106-110]

Adequate nutrition is essential for healing and is provided as total parenteral nutrition, enteral feeding, or a combination of both. Enteral feeding has been shown to be safe and effective during ECMO in all groups of patients and may limit the need for total parenteral nutrition with its associated complications.[111,112]

Maintaining strict fluid balance in critically ill patients is popular, and patients undergoing ECMO are no exception. The use of diuretics, concentrated drug infusions, and hemofiltration in patients with renal insufficiency is another important aspect of patient care. Renal failure, hypervolemia, and fluid overload are frequently seen in patients undergoing ECMO. The use of continuous renal replacement therapies (CRRTs) has become commonplace during ECMO, to maintain fluid balance, support failing kidneys, and potentially clear "bad humors" from the blood. One of the proposed mechanisms for the development of acute renal failure (ARF) in patients undergoing ECMO is a reduction in the pulsatile character of renal perfusion. Circuit-associated hemolysis in patients receiving CRRT also can perpetuate ARF. Techniques for providing CRRT are to connect a hemofiltration filter into the ECMO circuit and to control the ultrafiltrate volume using an intravenous infusion pump or approved continuous renal replacement systems. Patients receiving CRRT during ECMO have decreased survival, but this is also true in CRRT recipients who do not undergo ECMO. Few survivors have long-term renal failure. One single-center review of 154 ECMO patients who received CRRT found that (1) neonates and pediatric patients had longer ECMO runs than those who did not (248 h versus 97 h neonates, $p < 0.0001$; 211 h versus 173 h, $p = 0.026$); (2) continuous venovenous hemofiltration (CVVH) use increased from 17% (1997-1999) to 59% (2005-2007); and (3) patients receiving CRRT during ECMO had reduced survival compared to those who did not receive CRRT (88% versus 44%, $p < 0.0001$)[110-117]

Another study that examined acute renal failure in patients who were undergoing ECMO and required CRRT noted that ARF was present in 70% of patients and CRRT was initiated in 58% of patients. The study concluded that the odds of developing ARF increased with duration of ECMO support. Patients undergoing ECMO in whom ARF developed had a 4.7-fold increase in the odds of in-hospital mortality.

One abstract noted that CRRT with CVVH was used in 27 (32%) of 84 pediatric patients undergoing ECMO, usually to maintain fluid balance. Overall survival was 75% for patients with respiratory failure. Of these 84 patients, 27 were matched for age, diagnosis, and PRISM III score with patients undergoing ECMO who did not receive CVVH. Improved fluid balance over time, less use of diuretics, and the tendency to reach caloric-intake goals more quickly were noted in patients undergoing renal replacement. No difference was found in survival (67% CVVH, 82% non-CVVH, $p = .352$), duration of ventilation after ECMO, or the need for potassium supplementation between groups. Data from the ELSO registry show that about 30% of pediatric and adult patients undergoing ECMO undergo renal replacement either by hemofiltration or dialysis, although elevations of creatinine greater than 1.5 were reported in only 15% of pediatric patients. Other adjunct extracorporeal therapies such as plasmapheresis or liver support systems also have been used successfully during ECMO.

The optimal ventilatory management for patients undergoing ECMO is not known, and each center may have its own preference for how to treat the lungs

during ECMO.[118-120] Minimizing further barotrauma or oxygen toxicity and providing an environment that promotes lung healing are basic goals. For neonatal patients undergoing venoarterial ECMO, most centers use ventilator settings with low peak inspiratory pressure (PIP) (25 to 30 cm H_2O), PEEP (5 cm H_2O), intermittent mandatory ventilation rate (6 to 12 breaths/min), and fraction of inspired oxygen (FiO_2, 0.21–0.30). Lung volume decreases dramatically with such settings in most patients undergoing ECMO, resulting in generalized opacification on the chest radiograph. Maintaining lung expansion and functional residual capacity with higher levels of PEEP (10 to 15 cm H_2O) was associated with shorter ECMO durations in one neonatal study, and this approach is used frequently at many centers. In older patients, use of PEEP with reduced peak airway pressures, low ventilator rates, and low concentrations of inspired oxygen is also the predominant method of support. Commonly, PEEP levels in the range of 5 to 15 cm H_2O, plateau pressures of no more than 25 to 30 cm H_2O, and breath rates of 10 to 12 with inspired oxygen concentrations between 30% and 40% are reported in the pediatric and adult ECMO literature. Spontaneous breathing and even removal of the endotracheal tube or early bedside tracheostomy are gaining popularity as clinicians become more comfortable with allowing their patients on ECMO to be awake and alert. Proponents of spontaneous breathing point out that the natural course of healing in acute respiratory distress syndrome (ARDS) is about 6 weeks, and during the fibroproliferative phase, unmeasurable tidal volumes during ECMO may be unmeasurable for weeks. Thus trying to open these consolidated lungs may create more harm than merely letting these patients recover lung expansion on their own. Bronchoscopy can safely provide intermittent evaluation to remove inspissated secretions or identify airway issues. Computed tomography can also be useful to identify lung pathology. In patients who show no signs of improvement over many weeks or who are being considered for removal from ECMO for futility, lung biopsy may prove useful. Although inherent risks from bleeding exist with biopsy, results can prove useful.[121,122]

Patients with barotrauma and persistent air leaks even at low distending airway pressures on ECMO are among those who may benefit the most from removal from ventilator support or a spontaneous breathing mode. Often, healing of ruptured parenchyma can occur within 48 to 72 hours.

At high flow rates in patients undergoing venoarterial ECMO, a minimal amount of blood is entering the pulmonary circuit. Manipulating ventilator settings, especially in patients with diseased lungs with impaired gas exchange, has little effect on blood gas tensions. Oxygenation and carbon dioxide elimination depend on the function of the ECMO circuit. With venovenous cannulation, less overall bypass is obtained, and the systemic oxygenation provided by ECLS is less than with venoarterial access. Arterial oxygen saturations are thus lower with venovenous support. Although the majority of patients do well with saturations in the 75% to 85% range, monitoring of adequate oxygen delivery by following lactate, venous saturation, urine output, metabolic acid-base balance, and mental status is recommended with these patients.

As the lungs heal, compliance and tidal volume increase. Radiograph of the lung fields gradually improves from atelectatic opacification to increasing lung aeration. Increasing the oxygenation and concentration of expired carbon dioxide also heralds

improved alveolar/capillary gas exchange. Evidence of decreasing pulmonary artery pressure (indicated by resolution of right-to-left intracardiac shunting or other echocardiographic information) may also signal that the patient is ready to be weaned from ECMO.

Maintaining patient comfort during ECMO can be a challenge, especially during prolonged ECMO runs. Routine medications such as morphine, fentanyl, midazolam, lorazepam, and other agents provide sedation and analgesia. Medications are known to be absorbed by the membrane lung, although the extent of changes with the newer systems in use today is unclear.[122-125] Patients can also become tolerant to sedatives over time. Drug dependence and withdrawal symptoms become major adverse events and prolong hospital stays in many ECMO survivors. Although anesthesia gas in the membrane oxygenator was used in the silicone lung, hollow fiber membranes are not appropriate for this use, as the gas may pass easily through the device into the room atmosphere. Alpha-2 agonists such as dexmedetomidine have also proved useful to decrease narcotic or benzodiazepine requirements. Multiple reports from European centers on the success of maintaining ECMO patients in an awake state have started a new era of ECMO care. Patient management now promotes maintaining ECMO patients in an awake, alert, and even mobile state to sustain muscle strength and tone. Rehabilitation while on ECMO is especially needed for patients who are bridging to lung or heart transplant. Nursing and family support play a major role in the success of providing ECMO with little sedation.[126]

Weaning From Extracorporeal Membrane Oxygenation

A patient can be weaned from ECMO in several ways.[127,128] The most common venoarterial mode of weaning involves reducing the ECMO flow rate in set increments every 1 to 2 hours, provided that arterial and mixed venous oxygen saturations remain adequate. Once ECMO flow is reduced to provide only about two-thirds of cardiac output, ventilator support is increased (PIP 20 to 30 cm H_2O, intermittent mechanical ventilation 20–30, PEEP 5 cm H_2O, and FiO_2 30% to 40%). Weaning continues to an ECMO flow of 50 to 100 mL/min in infants or an estimated 10% of cardiac output. If the patient remains physiologically stable with acceptable blood gas tensions at this low flow, the ECMO cannulas are clamped and the infant is observed while off ECMO support for a short time. If respiration and circulation remain stable during the trial, the cannulas are removed and conventional therapy is resumed. Quicker weaning methods involve decreasing ECMO flow in larger increments over shorter periods, similar to the way it is performed during cardiopulmonary bypass in the operating room. For venovenous patients with respiratory failure, FiO_2 to the membrane lung and sweep gas should be decreased to the point where the oxygenator is capped off to allow no gas exchange and to ensure that the native lung can provide adequate oxygenation and ventilation. Although some clinicians also reduce ECMO pump flow during venovenous weaning, it is not necessary to wean flow excessively or clamp a patient off ECMO, as blood flow is already following the native circulation and the heart is providing

the pumping to the body.

Decannulation

Decannulation involves removal of surgically placed cannulas and repair of the operative site, with or without vessel repair. Vessels used in traditional, open venotomy or arteriotomy ECMO often can be repaired at decannulation, although this approach is not used universally. Whether avoiding ligation or repairing cannulated vessels results in long-term improvement in blood flow or reduced risk of stroke from thrombosis or infarct is unknown. The longest follow-up study of repaired carotid vessels found restenosis or occlusion in 24%. Patients with reconstructed vessels had fewer neuroradiologic abnormalities and a smaller incidence of cerebral palsy than did unrepaired historical control subjects, although these data represent a small, single-center report and are not the result of a randomized study. Femoral vessels are sometimes accessed via a Gore-Tex or similar graft sewn into the side of the vessel. This graft is tied off at decannulation.

Percutaneously placed cannulas are merely withdrawn at decannulation while gentle pressure is applied to the site until hemostasis is obtained. Vessels accessed percutaneously are not usually ligated either at initiation or decannulation from ECMO. Femoral artery repair often is performed to ensure continued integrity of the vessel and limb perfusion.

Heparin is discontinued at decannulation, and normalization of coagulation usually occurs within a few hours. Protamine is rarely used for the reversal of heparin-induced coagulation effects at decannulation. Venous thrombosis may develop after ECLS has been discontinued, especially if femoral cannulation is used, which may be an additional reason why heparinization should not be reversed. Many clinicians favor some form of anticoagulation or antiplatelet medication following decannulation, especially in adult patients.

Complications

Complications that occur during ECMO can be mechanical or related to the particular patient.

Bleeding

Bleeding as a result of the systemic heparinization required with ECMO is the major complication associated with ECMO.[129-136] Whereas bleeding occurs predominantly from cannulation or surgical sites, intracranial hemorrhage is the most dreaded site for bleeding to occur. Intracranial bleeding occurs in approximately 11% of patients overall, with the rate highest in the neonatal patient and lowest in the adult population. Bleeding that occurs outside of the head that cannot be controlled with medical means requires surgical investigation. Although obvious risks accompany surgical intervention in a bleeding patient who has undergone systemic anticoagulation, many operative repairs have been accomplished during ECMO support. Initial attempts to control bleeding focus on decreasing the rate of heparin infusion and lowering activated clotting time levels. Limitation of heparin may put the circuit at risk for increased clotting, especially at lower flow levels. This risk must

be balanced against the bleeding risk.

Medications to help prevent clot breakdown in the patient also are used. Historically, aminocaproic acid, also known by the trade name Amicar, has been the predominant medication used during ECMO. An antifibrinolytic amino acid, Amicar, displaces plasminogen from fibrin and inhibits clot breakdown. Although one survey found that a wide range of doses are used, one common algorithm follows a dosage scheme of 100 mg/kg as a load followed by an infusion of 25 to 50 mg/kg/h. Although it has been used in ECMO centers for many years, a randomized controlled trial of Amicar versus placebo in neonates found no difference between groups in the need for transfusion or the need for circuit changes due to thrombosis.[131] Aprotinin has also been used to prevent or limit bleeding. A serine protease inhibitor, aprotinin is an antifibrinolytic agent that inhibits protein C and factors Va and VIIIa in the extrinsic coagulation pathway and inhibits the intrinsic pathway as well. It also preserves platelet function, reduces vascular permeability, and has been suggested to decrease the inflammatory response to cardiopulmonary bypass. Aprotinin has not been compared in a randomized fashion to Amicar or placebo during ECMO. Aprotinin is administered as a loading dose of 10,000 units/kg and is continued at an infusion rate of 10,000 units/kg/h. Reports in adult patients of an increase in renal failure and poor outcome in cardiac patients receiving aprotinin during bypass surgery have caused it to be removed from the market. Ongoing studies showing its potential antiinflammatory properties are causing some discussion as to its return to the market. Circuit thromboses may be noted with use of Amicar or aprotinin.[132]

Several reports of intractable bleeding on ECMO have commented on the benefits of factor VIIa, although the data regarding this medication are still too sparse to recommend it without further investigation. In one study, use of factor VIIa was noted to be effective in decreasing chest tube bleeding from 47 to 10 mL/kg/h in four patients with refractory hemorrhage.[133-135] Each patient received two doses of R factor VIIa (dose, 90 to 120 μg/kg) 4 hours apart. In another report, 92% of patients undergoing ECMO with bleeding responded to R factor VIIa therapy. A significant reduction in chest tube bleeding was noted, along with a significant reduction in the administration of blood products. Major thrombosis was noted in two of the patients who received R factor VIIa therapy.

Other centers have reported decreased bleeding with lower doses of R factor VIIa administration; they have administered 40 μg/kg and then increased the dose to 90 μg if bleeding continued. Anecdotal reports of thrombosis with factor VIIa are more frequent than those found in the literature, and thus careful assessment of the risks and benefits should be undertaken prior to factor VIIa use.

Use of antithrombin (AT) during ECMO has also become popular. An increase in off-label use of AT in children of 200%, almost exclusively in patients receiving ECMO, was noted in one report. Although physiologically, replenishment of abnormally low AT levels may make sense, there are few data to show this is effective in limiting bleeding, thrombosis, limiting heparin exposure, or changing outcome, except in small single-center reports. The expense of this medication is also an important factor to consider.

Discontinuation of heparin to help control intractable bleeding also can be beneficial and has been used for variable periods, up to 36 hours or more, without significant clotting in the ECMO circuit. Larger patients with faster ECMO flow rates

are more likely to tolerate discontinuation of heparin without significant clotting.[136] However, it is wise to have a backup circuit readily available if clotting does occur and the ECMO system requires an emergent replacement.

Infection

Infection is another potential complication of ECMO.[137-140] Colonization of indwelling catheters, selective adherence of bacteria to polyurethane surfaces, sequestration of bacteria from the body's normal antibody and phagocytic defense mechanisms, and the patient's prior debilitated state are all factors that may increase the risk of infection. Successful therapy may be difficult without eliminating invasive equipment, most significantly the ECMO catheters. Viral infection from blood transfusions may occur rarely. Although sepsis (which was either preexisting or developed as the patient underwent ECMO) was once seen as a reason to exclude patients from ECMO, support for severe septic shock is now common. The most recent guidelines for hemodynamic support of pediatric patients with septic shock note that ECMO should be considered in patients with refractory catecholamine-resistant shock.[140]

Long-Term Outcome

As increasing numbers of critically ill neonates and children survive, attention should be directed to resultant morbidity. Although some studies have been published, most have involved venoarterial neonatal ECMO survivors and few have focused on long-term multidisciplinary evaluations.[142-154]

Medical Outcomes

Despite the fact that severe respiratory failure is the most common indication for ECMO in the neonatal period, airflow obstruction in school-age and adolescent survivors is usually mild.[154] Patients with congenital diaphragmatic hernia (CDH) are a subgroup in which lung function seems to deteriorate as children get older.[161] Risk factors for persistent airflow obstruction after neonatal ECMO are a diagnosis of respiratory distress syndrome, CDH, prolonged duration of ECMO treatment, and chronic lung disease.[154,161,163,164] Sensorineural hearing loss (SNHL) is another physical problem that has been reported in neonatal ECMO survivors. Its prevalence varies among different studies,[150] and risk factors seem to be related to neonatal intensive care treatment such as use of aminoglycosides, neuromuscular blocking agents, and loop diuretics rather than the ECMO treatment itself. In a group of 169 neonatal ECMO survivors (both with and without acute kidney injury), proteinuria as at least one sign of chronic kidney disease or hypertension was observed in 54 children (32%) at a mean age of 8 years.[166]

Neurodevelopmental Outcomes

The greatest burden affecting quality of life and participation in society seems to arise from neurodevelopmental morbidity. This remains an understudied area.

When evaluating the results of different studies on neurodevelopmental outcome, it should be noted that standardized assessments cannot be performed in children with severe disabilities. In general, 5% to 10% of ECMO survivors are unable to

fulfill validated assessments that compare developmental outcome with that of healthy peers.

Data on motor function performance after neonatal ECMO are scarce, but problems in this domain occur in approximately 40% of children of preschool age. Most problems are seen with gross motor function. Deterioration of motor function performance has been shown in a longitudinal evaluation: The proportion of children with normal motor function performance declined from 73.7% at 5 years to 40.5% at 12 years.[163] Children with low parental socioeconomic status, those with intracranial abnormalities, and those who need prolonged initial hospitalization are at risk for motor function problems at a later age.

Despite an overall average cognition, however, many children (up to 50%) have special educational needs. Observed problems in neonatal ECMO survivors revealed that at school age children have problems with working speed, memory, impaired visual-spatial abilities, and sustained attention and concentration. Having intracranial abnormalities prior to or during ECMO treatment and severity of critical illness seem to be determinants of neuropsychologic outcome, although standardized and validated scores to express illness severity are currently lacking.[154]

Neonatal ECMO survivors may be at risk for neuropsychologic problems later in life due to impaired development of executive functioning skills, which are developed in early childhood and continue development into young adulthood. These skills are needed to develop academic, behavioral, and social functioning and to prepare for successful daily functioning (eg, starting a career).

Of 4000 pediatric respiratory ECMO patients listed in the registry through July 2009, 9% had intracranial infarct or hemorrhage found on computed tomography examination. Brain death occurred in 6% of the patients, and 6% of patients had reported seizures. Long-term neurologic outcome data are sorely missing in the pediatric population. Few centers maintain regular follow-up clinics, and patients often are referred for ECMO from distant sites, which makes follow-up difficult as well. In one report of 15 pediatric and four adult patients, 58% survived to discharge. Patients were evaluated with use of the Pediatric Cerebral Performance Category (which measures cognitive impairment) and the Pediatric Overall Performance Category (which measures functional morbidity). Overall, 64% of survivors had normal Pediatric Cerebral Performance Category scores, 27% had mild disabilities, and 9% had moderate cognitive disability. Functional morbidity was normal in 27%, whereas 45% had mild disability, 18% had moderate disability, and 9% were severely disabled. In another small series of 26 patients monitored 1 to 3 years after ECMO, 38% of preschool-age children were described as normal and 31% had observed abnormalities. Four patients (31%) who had prior neurologic dysfunction remained at baseline following ECMO. Among school-age children, 77% were described as normal by parental report. More specific neurologic follow-up in the pediatric age groups is needed.

In a review of patients undergoing cardiac ECMO at <5 years of age who were evaluated 2 years later, a mental score of 73 +/−16 (normal 100 +/−15) was noted, with eight patients (50%) having mental delay. Lactate on admission to the PICU and single ventricle anatomy were associated with death. Time for lactate to normalize on ECMO, inotrope score at 120 hours of support, and chromosomal abnormality accounted for 77% of the variance in mental score when evaluated by stepwise multiple regression. In another report of neonates who received venoarterial ECMO

and were tested at 5 years of age, normal development in all domains was noted in only 49%, although severe disability was only found in 13%. Patients with underlying congenital diaphragmatic hernia had the worst outcomes.[171]

Neurologic complications in cardiac patients who undergo ECMO parallel those of patients who have respiratory failure.[172,173] Brain death occurred in 4% of patients, 3% had intracranial infarct, and 6% had intracranial hemorrhage. Because many cardiac patients are in a state of prolonged low cardiac output or sudden cardiac arrest prior to ECMO, the ability to assess neurologic function once ECMO is instituted is vital. Paralysis and sedation should be minimized until a neurologic examination can occur. This information is especially important in patients who are being listed for transplantation to avoid transplanting a viable organ into an inappropriate recipient.

Implications

Because motor function problems deteriorate over time and problems with executive functioning and academic achievement are usually seen at school age and later on, a question arises concerning whether ECMO survivors grow into their deficits. This question cannot be answered from the currently available literature, but prolonged follow-up addressing these issues is of utmost importance to optimize participation in society as ECMO survivors age into adulthood. A proposal for domains that should be addressed during follow-up of ECMO survivors is shown in Table 59.4. Whereas most outcome research has been performed on ECMO survivors who have received venoarterial ECMO cannulation, the impact of venovenous support (which is becoming more frequent in all age groups) on outcome requires further investigation. Additional development of this area is vital for evaluating the quality of life and cost/benefit of ECMO in pediatric patients, and similar issues with long-term outcome in adult ECMO survivors also exist.

The Future

Interhospital transport of patients, either those for ECMO consideration or those for whom ECMO was initiated at a non-ECMO facility, has become more available with the advent of smaller systems that are easier to transport. Currently only a few facilities routinely provide this service; however, ECMO transport companies are emerging that will allow movement from center to center as patient needs dictate. One single-center report found no statistical difference in survival rates in patients for whom ECMO was initiated in their center compared with patients who underwent cannulation at an outside facility and were brought to their center while receiving ECMO support. The typical transport team consisted of an ECMO coordinator, pediatric cardiac surgeon, surgical assistant, and intensivist. The predominant mode of transport was by helicopter (75%). No patient died during transport.[175] Whether the use of ECLS will grow and the need for ECMO transport capabilities throughout the United States will increase is unknown at this time. The logistics involved with maintaining a transport service requires meticulous planning and heavy resource use, and it is expensive to maintain unless the transport volume is high. This is one area where regionalization or contracting with an experienced team of ECMO providers for this service might prove practical.

The use of ECMO in the neonatal patients with respiratory failure has been accepted medical practice for many years, although improved care and management of these patients have reduced the need for ECMO in this population. The current extension of ECLS systems to older pediatric and adult patients in a variety of clinical settings highlights the changes that have occurred in the ECLS environment. Progress in renal replacement, liver support, and plasmapheresis and the development of new cardiac support devices applicable to pediatrics also may expand the use of ECMO or related techniques overall. Additionally, the development of small, portable systems for cardiopulmonary resuscitation may herald a new age of extracorporeal support. Technical advances in ECLS equipment continue to make such support safer and more efficient.[176] Venovenous ECMO techniques have been refined and used successfully in patients from neonatal to adult age groups. Single-cannula, double-lumen catheters for venovenous ECMO may obviate the risks of arterial cannulation and offer the benefit of requiring only one surgical site for venous access. Research and technologic improvements may decrease the need for systemic anticoagulation and the risk of hemorrhagic complications. Until the day when medical science may make the need for extracorporeal life support obsolete, research into ways to make it safer and more efficient should continue.

SECTION IV

Central Nervous System

OUTLINE

CHAPTER 60

Structure, Function, and Development of the Nervous System

Michael Shoykhet, Robert S.B. Clark

PEARLS

- In humans, general central nervous anatomy is established by birth. However, the brain undergoes substantial postnatal development including changes in synaptic density and dendritic arborization, maturation of neurotransmitter systems, and experience-dependent modification of neuronal circuits. Thus critical illness– and critical care–related therapeutic and environmental factors can shape ultimate central nervous system development.
- Normal cerebral blood flow (CBF) changes significantly with age. For term human newborns, normal CBF is approximately 40 mL/100 g brain/min. CBF peaks around 4 to 8 years of age at approximately 100 mL/100 g brain/min, declining to adult values of 50 mL/100 g brain/min in late adolescents.
- Normal CBF regulation to changes in blood pressure, CO_2, and O_2 is operative from birth in term human newborns. While cerebrovascular reactivity to CO_2 and O_2 remains relatively unchanged with age, blood pressure–dependent autoregulation operates over a narrower blood pressure range in younger children than older children and adults.

The nervous system, unlike any other organ system in the human body, stands at the intersection of biology and philosophy. While composed of cells and governed by chemical messages like all biological systems, it comprises the essence of each individual as a human being. The former can be quantified and studied; the latter enters the realm of religion, philosophy, and spirituality. Indeed, in a "brain-centric" approach to pediatric critical care, it can be argued that all interventions are ultimately targeted at preserving and protecting the child's nervous system function. Thus knowledge of the structure and function of the nervous system, together with

understanding of the developmental processes that are active in children who become patients in the ICU, is essential to the practice of the pediatric intensivist. Furthermore, the impact of disease and injury in the context of the developing nervous system is only now beginning to be understood, with many new advances in diagnosis and treatment undoubtedly yet to come.

Major Cell Types

The nervous system contains two major cell types: neurons and glia. Neurons are responsible for the major operations traditionally ascribed to the nervous system: sensation, movement, thought, memory, and emotion, as well as homeostasis of bodily functions. Interconnected networks of neuronal cells carry out all brain and spinal cord–based behaviors. Glia, although significantly more numerous than the neurons, function to support neuronally based information processing and long-distance information transfer. Both neurons and glia are broad classes of cells, each containing a multitude of specialized cells dedicated to carrying out specific functions in the nervous system.

All neurons, regardless of type and location within the nervous system, contain several standard cellular components that allow them to receive, process, and relay information. The neuronal soma (cell body) contains the nucleus where genes are transcribed into mRNA, the endoplasmic reticulum where mRNA is translated into proteins, and a multitude of mitochondria for cellular respiration and adenosine triphosphate synthesis. Originating from the soma are two types of processes: a number of dendrites and a single axon. Dendrites are short, local processes specialized for receiving information transmitted from other neurons via chemical or electrical synapses (see later). The axon is the output of the neuron, carrying information in the form of action potentials to be received by other neurons, muscles, and many additional body organs, at distances up to meters away.

Glial cells are typically divided into microglia and macroglia. Microglia are phagocytic cells derived from peripheral macrophages and normally exist in a resting or quiescent state in the central nervous system (CNS). Microglia are activated by several physiologically relevant factors, including bacterial lipopolysaccharide in the setting of infection and thrombin in the setting of injury.[1] Whether microglial activation is neurotoxic or neuroprotective in these settings has yet to be fully characterized. In addition, activated microglia play an important role in the neuropathology of Alzheimer disease, HIV-associated dementia, and prion diseases. Therapeutic strategies targeting microglial activation are just now beginning to emerge in animal disease models[2-3] and human clinical trials.[4]

Macroglia comprise several distinct cell subtypes within the nervous system: astrocytes and oligodendrocytes in the CNS and Schwann cells in the peripheral nervous system (PNS). Astrocytes are by far the most numerous cell type in the brain, performing several vital functions. At the synapse, astrocytes regulate ion and neurotransmitter concentrations, contributing to the modern notion that the synapse is a tripartite structure consisting of the presynaptic and postsynaptic neurons and the astrocyte. At the blood-brain barrier (BBB), astrocytes direct their processes toward the endothelial cells and contribute to the proper development of tight junctions (see later). In contrast to the relatively diverse functions of astrocytes, oligodendrocytes' and Schwann cells' primary purpose is to provide myelination for

axons in the CNS and the PNS, respectively. Myelination ensures faithful signal propagation along the entire axonal length. Each oligodendrocyte contributes myelin to between 10 and 15 axons in the CNS; each Schwann cell envelops a single axon in the PNS. From a clinical perspective, disorders of myelination contribute significantly to a range of diseases observed in pediatric critical illness, including perinatal asphyxia-induced periventricular leukomalacia, Canavan disease due to mutation in the oligodendrocyte-specific aspartoacylase gene, and Guillain-Barré syndrome, caused commonly by autoimmune-mediated injury to peripheral nerve myelin sheaths.

Intercellular Communication in the Nervous System

Early descriptions of neuronal cell structure by Camillo Golgi and Ramon Cajal in the late 19th century gave rise to two diverging theories of neuronal communication. Golgi proposed that neurons form an interconnected reticulum, much like cardiac muscle cells, and communicate directly with each other via openings in their membranes. Cajal, on the other hand, argued that neurons are individual cells with contiguous cell membranes and that communication takes place chemically at the sites of contact between individual neurons. Despite the radically opposed views, both theories are now known to be correct and both mechanisms contribute to aspects of neuronal communication in the mammalian brain. Direct communication between neurons, known as the electrical synapse, is accomplished via gap junctions. Communication across cell membranes at sites where two neurons contact each other is accomplished using neurotransmitters, with the contact site known as the *chemical synapse.*

Electrical Synapses

At the electrical synapse, cell membranes of the adjoining neurons are tightly bound together into a gap-junction plaque.[5] Each plaque contains numerous channels made of connexin proteins. There are 24 known connexin genes in humans. Each channel consists of two hemichannels, with one on each cell membrane. Two hemichannels join together to form a functional gap junction between two neurons, allowing intercellular diffusion of ions and small molecules such as glucose, cyclic AMP, and ATP. Gap junctions thus allow neurons to share information about their metabolic and excitable states, providing a mechanism for large-scale regulation of energy demands and neuronal network dynamics. Additionally, gap junction channels close in response to lowered intracellular pH or elevated Ca^{2+} levels; because both events occur in damaged cells, paired hemichannels at the gap junction may function to isolate healthy neurons from those damaged during ischemia or trauma. Recent evidence suggests that unpaired hemichannels outside of the gap junction plaques may also contribute to ischemic neuronal cell death.[6]

Glia, like neurons, are also connected by gap junctions. For example, brain astrocytes form an interconnected cellular network, which allows long-distance propagation of calcium signals across many cells. Additionally, layers of myelin generated by oligodendrocytes in the CNS and by Schwann cells in the PNS are

linked by gap junctions. Myelin gap junctions provide structural stability to the myelin sheath and allow for rapid diffusion of nutrients and other substances across the sheath toward the underlying axon. In humans, mutations in gap junction protein connexin 32 result in X-linked Charcot-Marie-Tooth disease, a demyelinating neuropathy.[7]

Chemical Synapses

Neuromuscular Junction

The neuromuscular junction (NMJ) is one of the most widely studied examples of chemical synaptic transmission in the nervous system. The overall concept is deceivingly simple: An action potential at the presynaptic neuron releases a neurotransmitter that in turn activates ion channels on the muscle cell membrane, resulting in postsynaptic action potential. Yet every step in this process is exquisitely controlled and modulated in health and may be disrupted in disease. Our evolving understanding of the NMJ provides a critical window into synapse function and pathophysiology.

The NMJ consists of three distinct anatomic components: the presynaptic nerve terminal, the synaptic cleft containing the basement membrane, and the postsynaptic muscle fiber. The presynaptic nerve terminal originates from the myelinated axon of a motoneuron in the spinal cord. Lower motoneurons in the ventral gray matter of the spinal cord send their myelinated axons through the ventral root toward peripheral muscle targets. As the axon approaches the muscle fibers, it loses its myelin sheath and branches into a fine network of terminals, each approximately 2 μm in diameter. Each branch has several swellings along its course, termed *presynaptic boutons,* where the nerve makes synaptic contact with the muscle fiber. Presynaptic boutons are covered by terminal Schwann cells, which provide growth factors, recycle neurotransmitters, and may participate in recovery after nerve and muscle injury. Presynaptic boutons are positioned over specialized regions of the muscle cell membrane called the *end plate regions.* Furthermore, underlying each bouton is a specialized invagination of the cell membrane that contains a high concentration of nicotinic acetylcholine (ACh) receptors and voltage-gated Na^+ channels. The presynaptic bouton and end plate are separated by a 100 nm-wide synaptic cleft containing the basement membrane and extracellular matrix. The basement membrane anchors a number of proteins, including acetylcholinesterase, the enzyme responsible for rapid hydrolysis of ACh in the synaptic cleft.

Several distinct functional steps occur during synaptic transmission at the NMJ. First, the action potential arriving from the motor axon depolarizes the membrane in the presynaptic boutons, causing Ca^{2+} entry via voltage-gated Ca^{2+} channels on the presynaptic membrane. Ca^{2+} entry results in fusion of synaptic vesicles containing ACh with the presynaptic cell membrane and release of ACh into the synaptic cleft. ACh rapidly diffuses toward the postsynaptic membrane and binds to the nicotinic ACh receptor (nACh); two ACh molecules are required to activate the nACh receptor. On activation, the nACh receptor opens and allows both Na^+ and K^+ to flow through the ion pore. The inward Na^+ current, however, dominates over the outward K^+ current, resulting in net depolarization of the muscle membrane at the end plate. This so-called end plate potential propagates a short distance before encountering voltage-gated Na^+ channels. These Na^+ channels open when membrane potential

rises to a critical threshold value, allowing only Na^+ ions to flow into the cell and generating the all-or-none muscle action potential. Acetylcholinesterases in the synaptic cleft terminate the depolarizing action of ACh at the postsynaptic membrane by rapidly hydrolyzing ACh into acetate and choline.

A detailed understanding of diseases that affect synaptic transmission at the NMJ, as well as familiarity with clinical pharmacology as it applies to the NMJ, is essential in critical care. Specific diseases affecting the NMJ include toxin-mediated botulism and autoimmune disorders such as myasthenia gravis, Lambert-Eaton syndrome, and neuromyotonia. These are discussed in detail in Chapter 71 (see also Tseng-Ong and Mitchell[8] and Lang and Vincent[9]). Among the pharmacotherapies targeted at the NMJ are some of the most commonly used drugs in the pediatric ICU: neuromuscular blockers. Furthermore, a number of toxins either decrease (anticholinergic agents) or increase (acetylcholinesterase inhibitors) the amount of ACh available at cholinergic synapses, resulting in corresponding toxidromes (see Chapter 128).

Chemical Synapses in the Central Nervous System

Chemical synapses in the CNS operate on basic principles similar to those governing synaptic transmission at the NMJ, although the cadre of neurotransmitters and postsynaptic receptors is significantly more diverse in the CNS. Importantly, a given neuron in the CNS may synthesize and store more than a single neurotransmitter, but it releases the same set of neurotransmitters at all of its synapses (Dale's principle). CNS synapses are generally divided into asymmetric (Gray type I) synapses and symmetric (Gray type II) synapses on the basis of their appearance under electron microscopy. Physiologically, these correspond to excitatory and inhibitory synapses, respectively. Each neuron synthesizes its own complement of neurotransmitters, which are delivered to all synaptic contact sites in the axon and packaged into synaptic vesicles. When an action potential reaches the axon, Ca^{2+} currents cause the synaptic vesicles to fuse with the cell membrane, releasing neurotransmitters into the synaptic cleft. Neurotransmitters then act on their corresponding ionotropic and metabotropic receptors on the postsynaptic membrane. Ionotropic receptor activation leads to either a depolarizing, excitatory current or a hyperpolarizing, inhibitory current. These subthreshold currents are called excitatory and inhibitory postsynaptic potentials (EPSPs and IPSPs), respectively. Temporal and spatial summation of EPSPs in the dendritic tree of the postsynaptic neuron occasionally depolarizes the somatic membrane sufficiently to cross threshold and generate an action potential. One of the distinguishing features of chemical synaptic transmission in the CNS, compared with the NMJ, is its lack of reliability on a single cell level; an action potential in the presynaptic neuron does not necessarily cause a postsynaptic neuron to fire its own action potential. Such lack of determinism likely allows for individual differences in responses to the same stimuli. After interaction with the receptor, the neurotransmitter is cleared from the synapse by diffusion, active reuptake into the terminal, or enzymatic destruction, similar to ACh hydrolysis at the NMJ.

Neurotransmitter Systems

Several substances are employed for communicating information chemically between neurons in the nervous system or between a neuron and a muscle at the neuromuscular junction. These substances, called *neurotransmitters*, generally fall into three categories: amines, amino acids, and peptides (Table 60.1). Each neurotransmitter requires its own synthetic machinery and exerts specific actions on the postsynaptic target. Furthermore, neurons tend to be characterized anatomically, immunohistochemically, and functionally by the main neurotransmitter they use, allowing insight into the role of each neurotransmitter system in CNS function.

TABLE 60.1

Neurotransmitter Classes

Amines	Amino Acids	Peptides
Acetylcholine	γ-Aminobutyric acid	Substance P
Dopamine	Glutamate	*Vasoactive intestinal peptide*
Norepinephrine	Glycine	Dynorphin
Epinephrine		Enkephalins
Serotonin		*Neuropeptide Y*
Histamine		*Cholecystokinin*

Neurotransmitters that operative exclusively in the central nervous system are in normal font, those used in both the central and peripheral nervous systems are in *italics*, and those used exclusively in the peripheral nervous system are in **bold.**

Neurotransmitters

Acetylcholine

Acetylcholine is an amine that functions as a neurotransmitter at the NMJ, as well as in the CNS. At the NMJ, its actions are quick and precise, whereas in the CNS it functions as a slow, more global modulator of synaptic activity. Cholinergic CNS neurons include all the motoneurons in the spinal cord, as well as a number of cell nuclei in the brainstem reticular formation and the basal forebrain. Cholinergic neurons synthesize ACh using choline acetyltransferase (ChAT), which transfers an acetyl group from acetyl coenzyme A (CoA) to choline (Fig. 60.1A). Choline concentration in the extracellular fluid is the rate-limiting step in the reaction. Cholinergic neurons also synthesize acetylcholinesterase (AChE), the enzyme that breaks down ACh. AChE is released with ACh into the synaptic cleft, where it rapidly hydrolyzes ACh into acetic acid and choline.

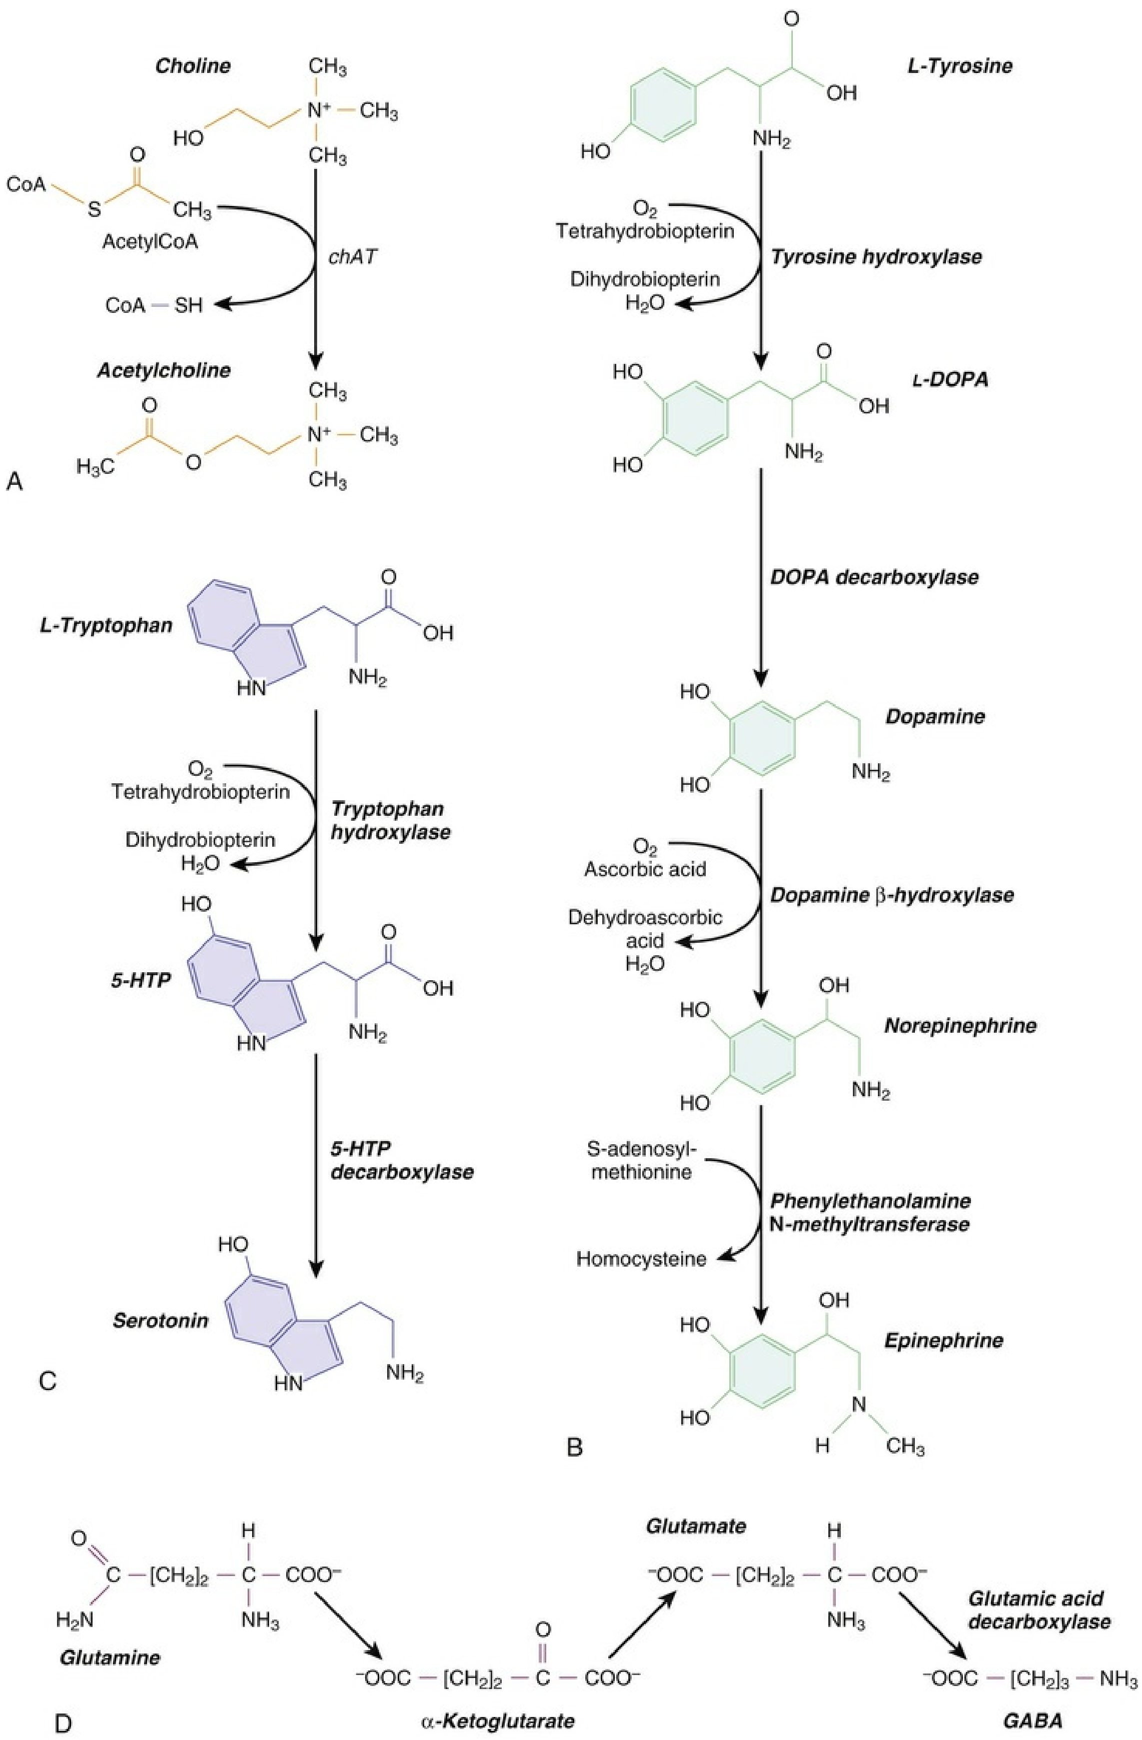

FIG. 60.1 Neurotransmitter structure and synthesis. (A) Acetylcholine. (B) Catecholamines. It should be noted that synthesis of norepinephrine and epinephrine requires dopamine as a precursor. (C) Serotonin, an amine

synthesized from tryptophan. (D) Glutamate and gamma-aminobutyric acid, amino acid derivatives.

Low concentrations of choline in the CNS have been associated with neurologic impairment during fetal[10] and postnatal life.[11] Thus choline supplementation represents an attractive therapeutic strategy in neurologic disorders characterized by decreased CNS choline. Interestingly, patients receiving long-term parenteral nutrition (TPN) occasionally develop choline deficiency, which has been associated with TPN-related liver failure[12] and, possibly, cognitive dysfunction. Hence choline supplementation in TPN-dependent patients may ameliorate some neurologic deficits.[13]

Catecholamines

Catecholamine neurotransmitters include dopamine, norepinephrine, and epinephrine. For all three, the initial starting point in biochemical synthesis is the amino acid tyrosine (Fig. 60.1B). Tyrosine is converted into an intermediate compound, called dopa, by tyrosine hydroxylase (TH). In dopaminergic neurons, dopa is converted into dopamine by dopa decarboxylase. Noradrenergic neurons, which use norepinephrine as a neurotransmitter, further convert dopamine into norepinephrine using dopamine β-hydroxylase. Finally, norepinephrine is converted into epinephrine by an enzyme phentolamine *N*-methyltransferase, which is found only in adrenergic neurons. Thus all neurons that synthesize catecholamines contain TH and dopa decarboxylase, but only noradrenergic and adrenergic neurons contain the synthetic enzymes required to produce norepinephrine and epinephrine, respectively.

Catecholamine-using neurons reside primarily in the brainstem. Dopaminergic neurons in humans are located in two mesencephalic nuclei: the substantia nigra and its medial neighbor, the ventral tegmental area. Dopaminergic neurons in the substantia nigra project primarily to the basal ganglia, where they are involved with initiation of voluntary movement. Ventral tegmental neurons send dopaminergic fibers to the amygdala and the cerebral cortex and participate in regulation of emotion, reward, and addiction. Brainstem noradrenergic neurons are located in the locus ceruleus and in the reticular formation. They project widely to the thalamus and cortex, as well as to the spinal cord, and play a significant role in arousal and vigilance. Adrenergic CNS neurons are located in the ventrolateral medulla and participate in temperature regulation via their projections to the hypothalamus.

Unlike ACh, which is cleared from the synapse by hydrolysis, catecholamines are cleared from the synaptic cleft by reuptake into the axonal terminal. Once inside the cell, catecholamines are either repackaged into vesicles or destroyed by monoamine oxidase (MAO). Pharmacologic manipulation of synaptic catecholamine concentrations plays a therapeutic role in the management of several disorders, such as depression and attention deficit-hyperactivity disorder (ADHD). Furthermore, recreational drugs affecting catecholamine concentrations at the synapse continue to gain popularity and to grow in number. Therapeutic uses include treatment of severe depression with MAO inhibitors, which inhibit catecholamine breakdown, and treatment of ADHD with amphetamines, which interfere with dopamine transport and increase dopamine concentrations. Recreational drugs include amphetamine and its analogs, along with cocaine, a selective norepinephrine

transporter blocker. Excess catecholamine levels at the synapse result in sensations of euphoria, increased energy levels, improved focus, anxiety, paranoia, and jitteriness. Notably, hypertensive crises leading to myocardial infarction and stroke may occur with use of cocaine, amphetamines, and MAO inhibitors.

Serotonin

Serotonin is an amine neurotransmitter synthesized from the amino acid tryptophan in a two-step process (Fig. 60.1C). First, tryptophan is hydroxylated by tryptophan hydroxylase to form 5-hydroxytryptophan (5-HTP). 5-HTP is then decarboxylated by 5-HTP decarboxylase to form serotonin, also known as *5-hydroxytryptamine* (5-HT). After 5-HT is released at the synapse, it is cleared by a specific serotonin reuptake transporter. Serotonergic neurons are located in the rostral and caudal raphe nuclei in the brainstem. Rostral raphe neurons innervate the cerebral cortex, including the limbic system, where serotonin levels help regulate mood and attention. Caudal raphe neurons project to the brainstem and spinal cord, where they are involved in regulation of general arousal and pain perception, respectively. Importantly, dysfunction of the serotonergic pathways originating in the raphe nuclei has been linked with sudden unexplained infant death (SUID).[14] Additionally, serotonin levels play a key role in depression, giving rise to an entire class of drugs in clinical use called selective serotonin reuptake inhibitors (SSRIs). SSRI abuse or overdose is rare but may result in patients presenting with the potentially life-threatening "serotonin syndrome," characterized by hypertension, tachycardia, mental status changes, myoclonus, and severe hyperthermia. The latter may lead to shock, rhabdomyolysis, renal failure, and death. The serotonin syndrome is particularly likely to occur when SSRIs and MAO inhibitors, inadvertently or intentionally, are taken together. Treatment includes serotonin antagonists, blood pressure control with either adrenergic antagonists or agonists as clinically indicated, and temperature control with benzodiazepines and neuromuscular blockade.

Amino Acids

Neurotransmitters derived from common amino acids include glutamate, gamma-aminobutyric acid (GABA), and glycine. These are among the most widely distributed neurotransmitters in the CNS. Glutamate and glycine exist as amino acids in all cells, where they are used as protein building blocks. Glutamatergic and glycinergic neurons have the additional capacity to package glutamate and glycine, respectively, into synaptic vesicles and release them at the synapse. GABA must be synthesized from glutamate via an additional reaction catalyzed by an enzyme glutamic acid decarboxylase (GAD) (Fig. 60.1D). Only GABA-ergic neurons contain GAD.

Glutamate is generally an excitatory neurotransmitter, whereas GABA and glycine are inhibitory. Excitatory glutamatergic neurons exert their influence both locally and over a long distance, depending on the shape of their axons. Inhibitory neurons, on the other hand, tend to exert local inhibitory control over neuronal circuitry either in the brain (GABA) or spinal cord (glycine). A major exception is cerebellar Purkinje cells, which are GABA-ergic but project over long distances to the brainstem, thalamus, and cerebral cortex (see later).

Adenosine, Peptides, and Nitric Oxide

In addition to the "classic" neurotransmitters described earlier, a number of substances have been documented to mediate or modulate information transfer between neurons. These include adenosine triphosphate (ATP) and adenosine, which at the synapse is a metabolite of ATP released in the synaptic vesicle. ATP modulates neuronal excitability such that energy may be conserved during times of ATP depletion. Adenosine functions as a neurotransmitter in the autonomic nervous system (ANS), in the basal ganglia, and at some cortical synapses. It also modulates the respiratory rate, and adenosine antagonists, such as caffeine, are used to treat apnea and bradycardia of prematurity. In addition to ATP and adenosine, a number of peptides can be released in synaptic vesicles, including substance P, vasoactive intestinal peptide (VIP), endogenous opioids, and endogenous cannabinoids. These peptides are involved in pain sensation and perception (substance P and opioids), modulation of vascular tone (VIP), and as yet uncharacterized processes (cannabinoids).

Finally, several gaseous molecules function as neurotransmitters. These include nitric oxide (NO), carbon monoxide (CO), and possibly hydrogen sulfide. NO, the most thoroughly studied of the gaseous neurotransmitters, is produced by brainstem neurons in the nucleus tractus solitarius, where it interacts with *α*-amino-3-hydroxyl-5-methyl-4-isoxazole-propionate (AMPA)-type and *N*-methyl-D-aspartate (NMDA)-type glutamate receptors and regulates cardiovascular function.[15] Hydrogen sulfide is produced from the amino acid cysteine and may influence cellular redox state and glutamatergic transmission.[16] Intriguingly, hydrogen sulfide induces a suspended animation-like state in animals[17] and may be protective after resuscitation from cardiac arrest.[18]

Neurotransmitter Receptors

Nicotinic Acetylcholine Receptors

Nicotinic ACh receptors are ligand-gated ion channels, related structurally and functionally to $GABA_A$ channels and a subset of serotonin receptors. Five transmembrane subunits comprise the nAChR and form a central pore that allows ionic currents to pass. There are two subunit classes, *α* and β, with multiple members in each class. nAChR is generally a heteromer, but homomer channels have been described. Each nAChR binds two acetycholine molecules, with affinity for ACh and nicotine dependent on subunit composition. The receptor exists in three distinct states: closed, open, and desensitized. In the closed position, no ionic current passes through the central core. When an agonist, such as ACh or nicotine, binds the nAChR, the receptor opens, becoming permeable to monovalent and divalent cations. After a short period of time, the receptor spontaneously closes. On continued exposure to an agonist, however, the nAChR assumes a permanently closed, or desensitized, conformation.[19] As discussed earlier, nAChRs mediate neuromuscular coupling at the NMJ. In addition, nAChRs are widely distributed in the CNS, where they perform a variety of functions depending on subunit composition and location.

In the CNS, unlike at the NMJ, nAChRs are permeable to both Na^+ and Ca^{2+}. In neurons, however, nAChR-evoked Ca^{2+} current exceeds the Na^+ current twofold to

tenfold. The greater Ca^{2+} permeability indicates that nAChRs mostly modulate synaptic transmission and release of other neurotransmitters. Indeed, although direct nAChR-dependent responses have been observed in the hippocampus and the developing visual cortex, overwhelming evidence points to nicotinic receptors playing the role of modulator in the CNS. Their wide distribution in the CNS with locations presynaptically, postsynaptically, and extrasynaptically further supports that role. Activation of presynaptic nAChRs enhances release of ACh, dopamine, glutamate, and GABA. Coupling of enhanced glutamate release with nAChR-dependent increase in intracellular Ca^{2+} suggests that nAChRs participate in synaptic plasticity during learning. Postsynaptic and extrasynaptic nAChRs regulate excitability and signal propagation in neuronal circuits. In the hippocampus, for example, nAChR activation leads to increased release of GABA from inhibitory interneurons, which decreases the excitability of hippocampal pyramidal neurons. Nicotinic receptors also interact with the dopaminergic system in regulating neuronal circuitry in the basal ganglia and the limbic system. Thus nicotinic receptors have been implicated in not only learning and memory but also regulation of addiction and reward. Furthermore, loss of cholinergic neurons represents one of the distinguishing neuropathologic features of Alzheimer disease, and cholinesterase inhibitors are widely used to improve cognition and memory in Alzheimer patients.[19] In pediatrics, a mutation in nAChR is responsible for a specific clinical epilepsy phenotype, called autosomal dominant nocturnal frontal lobe epilepsy.[20] Seizure onset usually occurs around 12 years of age in otherwise healthy children. Seizures originate in the frontal lobe and occur predominantly during non-REM sleep.[21] The mutant nAChR is more sensitive to ACh than the wild-type receptor, suggesting that cholinergic medications should be avoided in these patients.

Muscarinic Acetylcholine Receptors

Muscarinic ACh receptors (mAChRs) comprise a group of metabotropic receptors that link ACh exposure at the surface with G protein activation inside the cell. There are five distinct subtypes of mAChRs, designated M_1 through M_5, and these subtypes are divided into two broad classes on the basis of the identity of the G protein with which they interact. M_2 and M_4 mAChRs couple with G_i proteins, inhibit adenylyl cyclase activity, and reduce intracellular cAMP levels. M_1, M_3, and M_5 receptor subtypes couple with G_q proteins and increase intracellular Ca^{2+} levels via activation of phospholipase C.[22] In the CNS, the M_1 mAChR is the most abundant subtype, located on neurons in the cortex, thalamus, and striatum.[23] mAChRs are also present in the PNS in the sweat glands and organs of lacrimation and salivation, as well as in the heart, where they mediate the parasympathetic control of heart rate and contractility. Muscarinic AChRs thus mediate many of the systemic effects of organophosphate exposure and nerve gas poisoning.[24]

Glutamate Receptors

Glutamate is the major excitatory neurotransmitter in the central nervous system. In mammals, it depolarizes postsynaptic neurons by binding to three types of ionotropic glutamate receptors (iGluR), each of which is characterized by different affinities for synthetic analogs, different selectivity to ions, and different time course

of the current that is permitted to pass through the cell membrane. The three types of iGluR are the AMPA receptor, NMDA receptor, and kainate receptor. All three channel types are widely present throughout the CNS, with AMPA and NMDA channels mediating the bulk of the excitatory transmission. At present, the function of the kainate channel remains to be clearly defined.

AMPA and NMDA receptors differ from each other with respect to ion permeability and time course of ion flow through the channel. On binding of glutamate, AMPA receptors open their pores, which are permeable to Na^+ and K^+ ions. At the negative resting potential of the neuronal cell membrane, Na^+, driven by the electrochemical gradient, flows into the cell and causes a large, fast depolarization. AMPA receptors are generally impermeable to Ca^{2+}, although more recent findings indicate that Ca^{2+}-permeable AMPA receptors do exist and may significantly contribute to pathology observed in ALS and stroke.[25] In contrast, NMDA receptors are universally permeable to Ca^{2+}, as well as to Na^+ and K^+, generating a slow inward depolarizing current. NMDA receptors possess a unique property, however, that allows them to pass current only when the neuronal membrane is already depolarized. This property, termed *voltage-dependence,* stems from Mg^{2+} ions blocking the entry pore of the NMDA channel at negative membrane potentials even in the presence of glutamate. As the neuron depolarizes further, mostly due to current flow via the AMPA receptor, the Mg^{2+} block is relieved and Ca^{2+}, as well as Na^+, flows into the cell. Once inside the cell, Ca^{2+} ions mediate a multitude of effects, from modifying protein phosphorylation and gene expression to overt *excitotoxicity* and cell death. NMDA receptors are thus thought to function as coincidence detectors, linking events at the cell membrane (eg, AMPA receptor-mediated depolarization, with long-term changes in synaptic strength and gene expression in the neuron).

In addition to directly modulating current flow via the ionotropic channels, glutamate modulates effector molecules within the neuron by binding to a diversity of G protein–linked metabotropic glutamate receptors (mGluRs). Eight mammalian subtypes of mGluR are divided into three categories on the basis of sequence homology and coupling to secondary effector systems.[26] Group I mGluRs (mGlurR1 and mGluR5) are localized at the edge of the postsynaptic neuronal membrane and are positively coupled with phospholipase C (PLC) via the G_q protein. Group II and III mGluRs are located on the edge of the presynaptic neuronal membrane and are negatively coupled with adenylyl cyclase (AC) via the G_i protein. All three groups are activated only when excess glutamate spills out of the synaptic cleft and diffuses toward mGluRs located at the periphery of the synaptic membrane.

Differential secondary messenger coupling and synaptic localization of the three mGluR groups point to their divergent roles in regulating neuronal function. Binding of glutamate to group I mGluRs leads to activation of PLC, which releases two secondary messengers—diacylglycerol (DAG) and inositol triphosphate (IP_3)—from the membrane phospholipid phosphoinositol 1,4,5-bisphosphate (PIP_2). DAG activates protein kinase C in the neuronal membrane, whereas PIP_2 diffuses toward its receptor on the internal cell membrane and triggers a massive Ca^{2+} release into the cytoplasm. Downstream events lead to (1) modulation of K^+ currents, resulting in increased neuronal excitability, and (2) potentiation of glutamate-dependent current at NMDA receptors specific to the synapses at which excess glutamate release has

occurred. Group I mGluRs thus participate in activity-dependent strengthening of synaptic connections and play a significant role in learning and memory.

In contrast, group III, and probably group II, mGluRs on presynaptic neurons provide a negative feedback loop by inhibiting glutamate release. When glutamate binds to group III mGluRs, an inhibitory G protein (G_i) is activated. It then functions to decrease AC-mediated production of cAMP. A decrease in cAMP leads to lower Ca^{2+} concentrations at the presynaptic neuronal membrane and decreased synaptic vesicle fusion. The net effect is a decrease in the amount of glutamate released at the synapse and a reduction in synaptic transmission. Recently, mGluRs have emerged as a major therapeutic target due to the multitude of effects they exert on synaptic transmission. Their extrasynaptic location presumably will allow newly developed pharmaceutic agents to maximize therapeutic value and minimize unwanted side effects.[27]

$GABA_A$ and $GABA_B$ Receptors

GABA is the major inhibitory neurotransmitter in the brain. Like glutamate and ACh, it binds two distinct classes of GABA receptors; $GABA_A$ receptors are ionotropic, and $GABA_B$ receptors are metabotropic. Both receptor classes are involved in regulation of physiologic and pathologic states, and pharmacologic manipulation of GABA receptors plays a major role in the management of pediatric critical illness.

$GABA_A$ receptors are chloride channels. At the normal resting membrane potential, opening of the $GABA_A$ receptor allows chloride ions to flow into the cell down their electrochemical gradient. Influx of negatively charged Cl^- ions results in hyperpolarization of the cell membrane. In neurons, membrane hyperpolarization decreases the probability that the neuron will reach threshold and fire an action potential. Thus on an individual cell level, GABA decreases neuronal activity via the $GABA_A$ receptor.

$GABA_A$ receptors are heteropentamers, similar in structure to the nAChRs. At least eight subunit classes exist in mammals, including humans, and each class consists of several members, allowing for a staggering 150,000 possible subunit combinations to create one functional $GABA_A$ receptor. Only 500 combinations are known to exist, and most receptors contain a various complement of the α, β, and γ subunits.[28] Most $GABA_A$ receptors cluster at postsynaptic densities, and such clustering appears to depend on presence of the γ subunit. However, a subset of the $GABA_A$ receptors, in particular those containing the δ subunit, localize to extrasynaptic sites, mediate tonic levels of inhibition in the brain, and may underlie the pathophysiology of absence seizures.[29]

The pharmacology of the $GABA_A$ receptor is of particular relevance in critical care because the two classes of first-line anticonvulsants and anxiolytics in clinical practice—the benzodiazepines and the barbiturates—allosterically modulate the $GABA_A$ receptor. GABA itself binds the receptor at the junction of the α and β subunits. Benzodiazepines bind the $GABA_A$ receptor at a different site, classically between the α and γ_2 subunits, and, in the presence of GABA, increase the frequency with which the chloride channel opens. Barbiturates, in contrast, bind at yet a

different site and increase the duration of the open state in the presence of GABA. Thus both benzodiazepines and barbiturates increase the efficacy of endogenous GABA in hyperpolarizing the cell membrane. A major difference between the two drug classes is that at increasing concentrations, barbiturates, but not benzodiazepines, become direct GABA agonists and can open $GABA_A$ channels independent of endogenous GABA release. Hence barbiturates have a significantly narrower safety window compared with benzodiazepines.

Additional $GABA_A$ receptor ligands of clinical importance include (1) general inhalational anesthetics, which are thought to modulate tonic inhibition via the δ subunit–containing receptors; (2) alcohol, although its mechanistic action is poorly understood; and (3) flumazenil, a competitive benzodiazepine antagonist used clinically to reverse benzodiazepine overdose.

$GABA_A$ receptor mutations contribute to several known disease states in humans. Two different point mutations on chromosome 5, both affecting the γ_2 subunit, are associated with development of febrile seizures and generalized epilepsy, as well as with a link between the two conditions.[30-31] In patients with temporal lobe epilepsy, $GABA_A$ receptor expression is altered in hippocampal neurons[32] and GABA-evoked responses actually depolarize, rather than hyperpolarize, neurons in excised tissue (see also Developmental Processes section later in the chapter).[33] $GABA_A$ receptor dysfunction is also thought to contribute to anxiety, panic disorder, schizophrenia, and sleep disturbances.[34] Thus pharmacologic modulation of $GABA_A$ receptor function represents an active area of research and novel drug development.

$GABA_B$ receptors are heterodimeric proteins that activate G protein–coupled second messenger systems upon interaction with GABA at the membrane.[35] The $GABA_{B1}$ subunit binds GABA at the cell membrane, while the $GABA_{B2}$ subunit interacts with the G protein on the cytosolic surface. $GABA_B$ receptors are widely distributed throughout the CNS but are particularly abundant in the thalamus, cerebellum, and hippocampus. They can be located both presynaptically and postsynaptically. Presynaptic $GABA_B$ receptors allow G protein–coupled Ca^{2+} influx into the cell and lead to feedback inhibition of transmitter release. Postsynaptic $GABA_B$ receptors function as K^+ channels by allowing a slow, G protein–dependent K^+ current to leak out of the cell and lead to cell hyperpolarization (because positive ions have left the inside of the cell membrane).[36]

Baclofen is the only pharmacologic $GABA_B$ receptor ligand in current clinical use. It directly activates the $GABA_B$ receptor and, through its action in the spinal cord, leads to reduction in muscle tone. Thus it is used primarily to relieve spasticity after CNS injury. When administered systemically, it has a significant side-effect profile, including hypotension and bradycardia.[35] Systemic side effects have been minimized with intrathecal administration via an indwelling catheter and pump.[37,38] Indeed, intrathecal baclofen infusion has emerged as an alternative to the more invasive dorsal rhizotomy in the treatment of spasticity refractory to medical therapy in pediatric patients.[39] Although intrathecal baclofen delivery systems are effective, they have a 10% to 20% failure rate over time. When an intrathecal baclofen pump fails, patients can develop baclofen withdrawal symptoms characterized by agitation, increasing spasticity and dystonia, hypertension, tachycardia, hyperthermia, and potentially death.[39] Thus baclofen withdrawal should be

considered in the differential diagnosis of an agitated child with an indwelling baclofen pump.

Major Anatomic Organization of the Nervous System

The nervous system in mammals is organized along an evolutionarily conserved axis. It can be divided anatomically and functionally into the central and peripheral nervous systems. Broadly speaking, the CNS consists of the spinal cord and brain inside the skull. All other components, such as nerves after they leave the spinal canal or exit the brain, as well as autonomic ganglia in the body, comprise the PNS. The general subdivisions are shown in Fig. 60.2. The following sections focus on well-defined functions of these subdivisions as well as on their clinical relevance in pediatric critical care medicine.

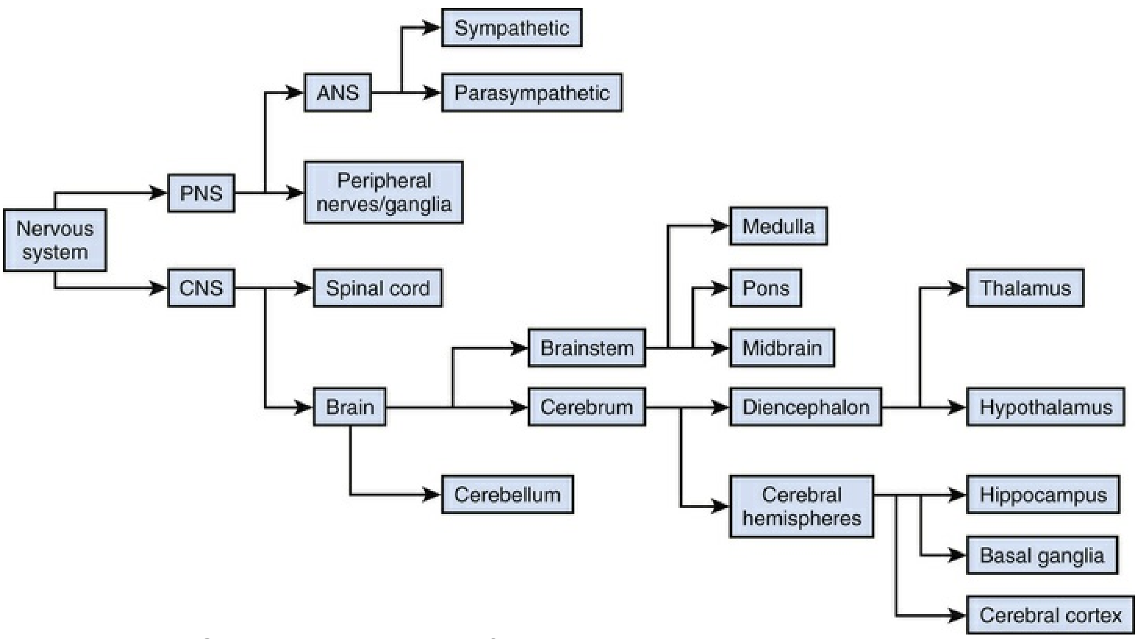

FIG. 60.2 General subdivisions of the nervous system. (Modified from Nolte J. The Human Brain. An Introduction to Its Functional Anatomy. 3rd ed. St. Louis: Mosby–Year Book; 1993.)

Central Nervous System

Spinal Cord

The spinal cord is organized into segments delineated by the exiting spinal nerves. In humans, there are 31 segments: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal.[40] The first seven cervical nerves exit the spinal canal above the corresponding vertebra, that is, the C1 nerve exits between the occiput and the C1 vertebra (the atlas). Because in humans there are only seven cervical vertebra and eight cervical nerves, the last cervical nerve, C8, exits the spinal canal between C7 and T1. From T1 on, each corresponding spinal nerve exits the spinal cord below its

corresponding vertebra, that is, the T12 nerve exits between T12 and L1. Early in fetal life, the spinal cord extends throughout the entire length of the spinal canal. Beginning in gestation week 12, the growth rate of the vertebrae exceeds that of the spinal cord, such that by birth in humans, the spinal cord ends at L3. During postnatal development, further differential growth occurs, and in adults, the spinal cord ends more rostrally, between L1 and L2. The nerve roots continue to exit the spinal canal through their corresponding foraminae, such that the caudal spinal roots extend past the end of the spinal cord toward their exit points and form the cauda equina. The end of the spinal cord forms an important landmark during development because the lumbar puncture must be performed below the spinal cord in order to avoid severe injury. Hence in infants, the preferred location of the lumbar puncture is between L4 and L5 vertebrae, with an alternate site between L3 and L4. In adults, it is safe to perform the lumbar puncture between L3 and L4, with both the L2/L3 and the L4/L5 intervertebral spaces as alternative sites.

Spinal cord lesions result in two general subsets of neurologic deficits: those caused by interruption of ascending information flow toward the brain and those caused by interruption of descending brain control of the spinal cord circuitry and the PNS. Thus complete spinal cord transection leads to loss of sensation and muscular paralysis below the level of the lesion due to injury to the ascending sensory pathways and descending motor pathways, respectively. Immediately after the transection, paralysis is flaccid with loss of deep tendon reflexes, characteristic of spinal shock (not to be confused with neurogenic shock, see later). After a period of time, paralysis becomes spastic, with increased muscle tone and hyperactive deep tendon reflexes, due to disrupted inhibitory control of spinal cord circuitry by the brain's motor centers.

Medulla

The medulla extends rostrally from the spinal cord in the rough shape of an ice cream scoop.[40] The closed "handle" portion contains an enclosed central canal contiguous with that in the spinal cord. The open "scoop" portion is located rostrally where the central canal opens into the fourth ventricle. The medulla gives origin to four cranial nerves (CN): the glossopharyngeal (CN IX), vagus (CN X), accessory (CN XI), and hypoglossal (CN XII). It also contains decussations (crossings) of two major fiber tracts. The postsynaptic fibers from the nuclei gracilis and cuneatus, which carry tactile information from the lower and upper parts of the body, respectively, cross the midline in the caudal medulla, giving rise to the sensory decussation. The pyramidal tracts, which contain fibers descending from the motor cortex into the spinal cord, decussate slightly more rostrally, giving rise to the pyramidal, or motor decussation. These decussations are responsible for the fact that the left half of the brain controls and senses the right half of the body, and vice versa. Thus in general, damage to brain structures above the decussation gives rise to contralateral symptoms, whereas damage below the decussation results in ipsilateral symptoms (except for the cerebellum as discussed later). Finally, the medulla contains the brain's respiratory control center, which is of paramount importance in determining brain death (see later). In the absence of neuromuscular blockade, complete apnea in response to rising $PaCO_2$ results only when the medulla has been extensively injured.

Although extensive damage to the medullary structures is often quickly fatal due to ensuing apnea, more localized injury produces a number of recognizable syndromes. Wallenberg, or lateral medullary, syndrome occurs when the territory supplied by posterior inferior cerebellar artery has been compromised and consists of loss of temperature and pain sensation on the contralateral side of the body and ipsilateral side of the face. Additionally, Horner syndrome and varying degrees of vertigo, dysphagia, and dysarthria can be present. The medial medullary syndrome (Dejerine or inferior alternating syndrome) results from injury to the territory supplied by the anterior spinal artery or, occasionally, the vertebral artery. It is characterized by weakness or complete hemiplegia and loss of tactile and vibratory perception on the contralateral side of the body, together with preservation of temperature and pain sensation in the body and full sensation in the face. Medullary injury also occurs as a life-threatening, albeit rare, complication of tonsillectomy and adenoidectomy.[41]

Pons

The pons extends from the medulla to the midbrain and is readily recognized by the massive, bulbous structure with horizontally oriented fibers on its ventral surface that gives rise to its name (from the Latin, *bridge*). The pons begins at the pontine-medullary junction, characterized by a groove from which the abducens (CN VI), facial (CN VII), and vestibulocochlear (CN VIII) nerves emerge. It extends rostrally to the point of emergence of the trochlear nerve (CN IV), where it transitions into the midbrain. The trigeminal nerve (CN V) exits from the lateral aspect of the pons approximately midway between the medulla and midbrain.

In addition to the cranial nerves, the pons contains several other important structures. Its eponymous bulb, called the *basis pontis,* is formed by bundles of corticopontine fibers that connect the cerebral cortex with ipsilateral pontine nuclei. Postsynaptic fibers originating in the pontine nuclei then cross the midline and form the middle cerebellar peduncle, which comprises one of the major input pathways into the cerebellum. Cerebellar output to the thalamus and other structures takes place via the superior cerebellar peduncle contained in the rostral pons. Additionally, the rostral pons contains the locus ceruleus (from the Latin, *blue spot*). Locus ceruleus neurons use norepinephrine as a neurotransmitter, innervate wide-ranging areas of the brain, and likely regulate sleep and arousal.

Injury to pontine structures is of significant relevance in the pediatric ICU (PICU). First, increased intracranial pressure (ICP) from any cause may result in compression of the medially located small abducens nerve (CN VI), leading to paralysis of the lateral rectus eye muscle and associated turning in of the affected eye. Abducens nerve palsy due to increased ICP may precede the notorious fixed and dilated pupil phenomenon observed when CN III is compressed during impending uncal herniation (see later). Second, damage to the rostral pons (or lower midbrain) results in decerebrate posturing, characterized by extension of both upper and lower extremities on painful stimulation. Importantly, decerebrate posturing corresponds to the motor score of 2 on the Glasgow Coma Scale (GCS) score. Finally, infarction of the basis pontis with sparing of the more dorsal pontine structures results in the "locked-in" syndrome. The locked-in state is characterized by complete paralysis of all voluntary muscles except the muscles of ocular movement and by complete cognitive awareness. Because the locked-in patient can communicate only via eye

gaze, recognition of the locked-in state by the physician requires extreme diligence in patients with brainstem lesions, lest the patient be misdiagnosed as comatose, with potentially dire consequences.

Midbrain

The midbrain is the most rostral and smallest of the brainstem structures. It is characterized by the presence of the bilateral inferior and superior colliculi on its dorsal surface. Additionally, the oculomotor nerve (CN III) emerges from its ventral surface, immediately below the temporal lobe of the cerebral hemisphere. The midbrain contains structures important for hearing, sound localization, and generation of saccadic eye movements. Furthermore, the substantia nigra in the midbrain contains neurons that use dopamine as their neurotransmitter. These dopaminergic neurons project to the basal ganglia, where dopamine release participates in initiation of voluntary movements, to the limbic system in the cerebral cortex, where dopamine plays a role in reward and emotion, and to the frontal and temporal cortices, indicating that dopamine affects thought and memory. Destruction of dopaminergic substantia nigra neurons underlies the pathology of idiopathic Parkinson disease in older individuals and of Parkinsonian symptoms in drug abusers exposed to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine, sometimes a contaminant in heroin preparations.

Two clinical phenomena of significant importance in pediatric critical care medicine arise from damage to midbrain structures. First, global injury to the midbrain results in decorticate posturing, characterized by flexion of upper extremities and extension of lower extremities in response to painful stimulation. Decorticate posturing corresponds to a motor score of 3 on the GCS. Second, the "blown" pupil universally recognized as a sign of increased ICP and impending transtentorial brain herniation results from compression of the oculomotor nerve (CN III) as it exits the midbrain. Pupillary dilatation results from compression and inactivation of the parasympathetic fibers that run on the outer surface of CN III and which are actually responsible for pupillary constriction. When these fibers are damaged, unopposed sympathetic stimulation arising from the cervical sympathetic ganglia results in a constitutively dilated pupil that cannot constrict in response to light stimulation, or in other words, is "fixed." Unilateral fixed and dilated pupil is an emergency that requires immediate medical and/or surgical intervention.

Reticular Formation

The brainstem reticular formation is not a separate anatomic structure but is instead distributed throughout the core of the brainstem from the medulla into the midbrain. It plays a fundamental role in arousal and consciousness, control of movement and sensation, and in regulation of visceral functions. A subset of the reticular formation neurons sends fibers to the intralaminar thalamic nuclei, which in turn project widely throughout the cerebral cortex. Damage to these ascending brainstem fibers, collectively called the *ascending reticular activating system,* results in loss of consciousness and coma, even in the absence of any damage to the cerebral hemispheres. Thus the cerebral cortex requires input from the brainstem to maintain awareness and arousal. In addition, the reticular formation contains neuronal circuits responsible for regulation of respiration, cardiovascular responses to blood

pressure and oxygen level modulations, and coordination of swallowing and other oromotor functions. Finally, complex reflexes such as walking and maintenance of body orientation with respect to gravity are coordinated by the brainstem reticular formation and may occur in the absence of input from higher brain regions. Immaturity of the brainstem reticular formation, in particular of its serotonergic component, has been implicated in the etiology of SUID.[14]

Cerebellum

The cerebellum overlies the majority of the brainstem and is separated from the cerebral cortex by a sheetlike reflection of the dura mater, called the *tentorium cerebelli.* Hence the brainstem and cerebellum are referred to as *infratentorial structures* while the cerebral cortex and the diencephalon are referred to as *supratentorial structures.* The cerebellum consists of a midline vermis and two large cerebellar hemispheres.[40] The outer surface of the cerebellum consists of a three-layered cortex, which includes the outer molecular layer, Purkinje cell layer, and granular layer. The molecular layer contains mostly axons and dendrites. The Purkinje cell layer contains the eponymous large GABA-ergic neurons that constitute the sole cerebellar output. Finally, the granular layer contains small granule cells that interact with other granule cells and with Purkinje neurons. In addition to the cerebellar cortex, each cerebellar hemisphere also contains a set of deep nuclei. From lateral to medial, these are the dentate, interposed, and fastigial nuclei.

Cerebellar function has traditionally been confined to regulation and coordination of movement of the eyes, head, and body in space. However, evidence from neuroanatomic and functional neuroimaging studies has suggested that the cerebellum, and in particular the dentate nucleus, plays a significant role in cognition, memory, and language.[42,43] Consequently, lesions in the cerebellum are characterized by ataxia, ipsilateral dysmetria, and intention tremor, as well as by scanning speech, in which each syllable is produced slowly and separately, and by disorders of memory and executive function.[43] In the PICU, cerebellar lesions are seen most frequently in the setting of infratentorial tumors but also occasionally in cerebellar strokes.

Diencephalon

The diencephalon consists of four major structures: thalamus, hypothalamus, subthalamus, and epithalamus. Of these, only the thalamus and the hypothalamus are discussed in detail as they serve crucial functions relevant to pediatric critical care medicine. The thalamus is the major relay station for all sensory information except olfaction as it travels from peripheral sensory organs to the cerebral cortex. For example, optic nerve neurons carrying visual information synapse onto neurons in the lateral geniculate nucleus in the thalamus, which process and transmit the signal to the primary visual cortex in the occipital lobe. Furthermore, the thalamus participates in coordination of motor activity via multiple neuronal loops that connect the cerebellum with the basal ganglia and the cerebral cortex.[43] Lastly, inhibitory thalamic nuclei such as the reticular nucleus (distinct from the brainstem reticular formation) are thought to participate in gating of attention and consciousness.[44]

Injury to the thalamus occurs frequently in both term and preterm neonates

exposed to hypoxia-ischemia at birth.[45] Additionally, thalamic necrosis is observed in infectious encephalitis, particularly that associated with the influenza virus[46,47] and *Mycoplasma pneumoniae*.[48] Vascular diseases, such as occlusion of the basilar artery or systemic lupus erythematosus, can result in thalamic injury that can occasionally be reversible.[49] Apparent life-threatening events have been rarely associated with thalamic lesions.[50] Thalamic damage is associated with a wide range of symptoms, including pure sensory loss due to destruction of sensory relay nuclei, acute abnormalities in mental status, labile emotions, and motor dysfunction.

The hypothalamus is located inferior to the thalamus and plays a major role in regulation of emotion, homeostasis, circadian rhythms, and ANS function. Most importantly, it controls hormone release in the pituitary gland via two separate pathways. Large hypothalamic neurons in the supraoptic and paraventricular nuclei project their axons via the pituitary stalk into the posterior pituitary lobe (neurohypophysis), where they release antidiuretic hormone (ADH) and oxytocin directly into the bloodstream. ADH promotes water reabsorption in the kidney, whereas oxytocin participates in parturition and milk secretion. Damage to the posterior pituitary produces diabetes insipidus. Hypothalamic projections into the anterior pituitary (adenohypophysis) also travel down the pituitary stalk and release a multitude of release-promoting or release-inhibiting factors into the pituitary portal vein.[40] These factors then control the release of all anterior pituitary hormones, including adrenocorticotropic hormone, thyroid stimulating hormone, growth hormone, prolactin, and luteinizing/follicle-stimulating hormone. Of these, only prolactin release is constitutively inhibited by the hypothalamus, while the release of all remaining pituitary hormones is under positive control. Thus transection of the pituitary stalk, as can occur during skull base and pituitary surgery,[51] results in panhypopituitary syndrome characterized by diabetes insipidus, hypothyroidism, cortisol deficiency, and hyperprolactinemia.

Damage to hypothalamic nuclei, in addition to disrupting control of the pituitary gland, also results in emotional lability, aggression, and extreme overeating or anorexia leading to rapid weight gain or loss, respectively. Thus overwhelming aggression combined with acute weight changes should raise suspicion for a hypothalamic tumor in a child.

Basal Ganglia

The basal ganglia are a set of deep nuclei that reside below the surface of the cerebral cortex and surround the thalamus. They are composed of the caudate, putamen, globus pallidus, substantia nigra, and subthalamic nucleus. The caudate receives most of its input from the prefrontal cortex and projects via the globus pallidus and thalamus back to the prefrontal cortex. It is thus involved with cognitive function and tends to be one of the nuclei that degenerate slowly over time after a hypoxic-ischemic insult to the cortex. The putamen receives most of its input from the somatosensory and motor cortices and, like the caudate, projects back to these cortices via the globus pallidus and thalamus. The putamen plays a major role in coordination of motor function. The globus pallidus serves as an inhibitory modulator in the cortex–basal ganglia–thalamus–cortex loop. Hence deep brain stimulation in the globus pallidus in patients with Parkinson disease results in resolution of motor symptoms attributable to hyperactivity in the loop, such as tremor and rigidity. The substantia nigra contains dopaminergic neurons that project

to the other nuclei in the basal ganglia and participate in initiation and coordination of voluntary movement.

The basal ganglia are the site of injury in multiple processes in pediatrics. They are often injured by hypoxia and hypoglycemia due to interruption of energy supply. Similarly, carbon monoxide poisoning effectively prevents oxygen delivery to the basal ganglia, resulting in characteristic neuroradiologic findings.[52] A number of metabolic diseases, including methylmalonic acidemia, Leigh disease, maple syrup urine disease, and glutaric acidemia type II, also result in degeneration in the basal ganglia. The basal ganglia accumulate iron and copper and consequently can be injured by iron overload or in Wilson disease. Finally, a juvenile form of Huntington disease presents with characteristic degeneration in the caudate nucleus.[52] Clinical signs of injury to the basal ganglia are often nonspecific: lethargy, irritability, and decreased mental status. Movement disorders such as dystonia or chorea can be seen early in the course of injury but are relatively uncommon, being more likely to emerge with chronic deterioration in basal ganglia function.

Cerebral Hemispheres

The cerebral hemispheres are the most rostral part of the CNS, and in humans and some other mammals, they are characterized by extensive folding of the cerebral cortex. The folding greatly expands the area of the cerebral cortex that can fit into the cranial vault. In humans, the cortical sheet has an area of 2.5 square feet when all the folds are flattened, yet the surface area of the adult skull is closer to 0.5 square feet. The folds consist of ridges termed *gyri* (singular, *gyrus*) and spaces separating the ridges termed *sulci* (singular, *sulcus*). Although the detailed organization of each gyrus and sulcus is quite individualized, the larger organizational features are common to all mammals.

Each cerebral hemisphere is divided into four lobes: frontal, parietal, temporal, and occipital (Fig. 60.3). The frontal lobe extends caudally from the rostral pole of the brain to the central sulcus and inferolaterally to the lateral sulcus. The parietal lobe begins at the central sulcus and extends caudally to the parietooccipital sulcus. Inferolaterally, the parietal lobe is bounded by the lateral sulcus and imaginary line connecting the extension of the lateral sulcus with the parietooccipital sulcus. The temporal lobe is delineated primarily by the lateral sulcus. Finally, the occipital lobe resides posteriorly to the parietooccipital sulcus. Each of the four lobes performs dedicated functions, some of which are symmetric, occurring in both hemispheres, whereas others are lateralized, specific to either the right or left cerebral hemisphere.

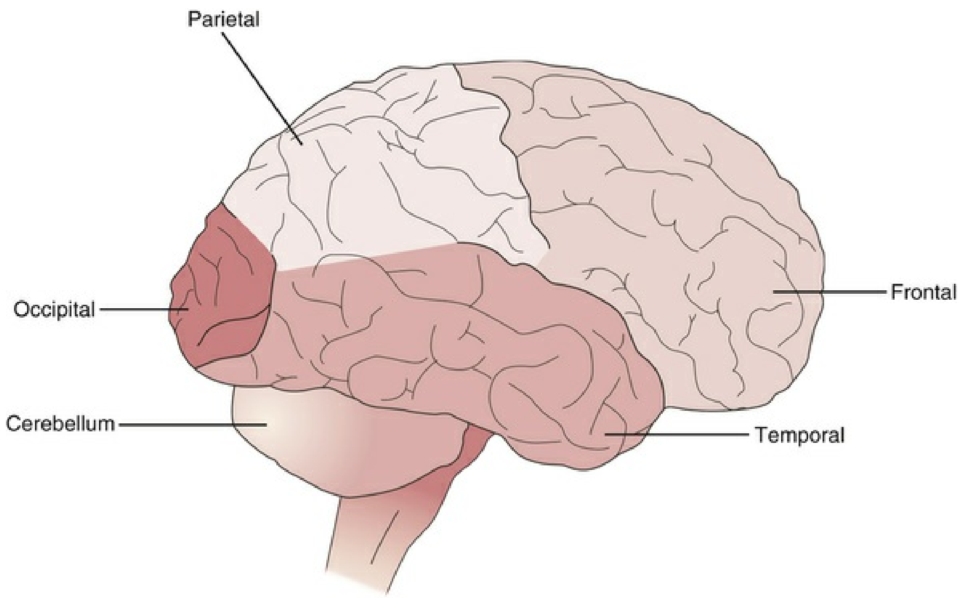

FIG. 60.3 General subdivisions of the human cerebral cortex. Note that the cerebellum is not part of the cortex but is labeled for clarity.

The frontal lobe is divided into four cortices, reflecting its functional organization. The primary motor cortex, located on the precentral gyrus, directly controls volitional movement on the contralateral side via upper motoneurons projecting to the lower motoneurons in the spinal cord. Moving rostrally, the premotor cortex is involved in planning, coordination, and initiation of movement. The most rostral part of the frontal lobe, the prefrontal cortex, is generally associated with personality and foresight/planning. Additionally, one side of the frontal lobe, usually the left, contains the Broca area on its inferolateral surface. The Broca area participates in the production of spoken and written language.

The parietal lobe contains the primary somatosensory cortex, which is located on the postcentral gyrus and which receives all tactile and proprioceptive sensory information from the contralateral side of the body. The parietal cortex posterior to the primary somatosensory cortex possesses quite lateralized functional areas, with cortex on the left usually involved with language processing and comprehension, and that on the right responsible for perception of space and special orientation. The occipital lobe is generally devoted to vision in humans, containing the primary visual cortex and several secondary visual areas. The temporal lobe, on the other hand, serves more diverse functions. It contains the primary auditory cortex, which receives all auditory stimuli from the periphery. The temporal lobe also encompasses the hippocampus and the limbic system, thus participating in learning, memory, and emotion.

Peripheral Nervous System

The peripheral nervous system is generally divided into two components: the somatic PNS, which includes the peripheral nerves carrying information to and from muscle and skin, and the visceral (or autonomic) PNS, which regulates homeostatic bodily functions and mainly innervates visceral organs such as the heart, lungs, and intestines. Dysfunction of both the somatic and the autonomic systems contributes to the breadth of pathology encountered in pediatric critical care medicine, thus

requiring the pediatric intensivist to be familiar with the basic organizational and functional principles of the PNS.

Somatic Peripheral Nervous System

The somatic PNS consists of efferent nerve fibers carrying information to muscle and skin, peripheral sensory receptors, and afferent nerve fibers carrying information from the periphery to the CNS. The efferent fibers emerge from neurons located in the spinal gray matter and exit the spinal cord via the ventral root. The afferent sensory fibers belong to neurons located in dorsal root ganglia, which send an axonal branch into the spinal cord via the dorsal root. The efferent and the afferent fibers travel together between the dorsal root ganglia and the target organ in the peripheral nerve. Diseases of the somatic PNS relevant to pediatric intensive care are generally disorders of myelination, such as Guillain-Barré syndrome, and are discussed in detail in Chapter 71).

Visceral or Autonomic Peripheral Nervous System

The autonomic nervous system regulates bodily functions that do not necessarily require conscious control or awareness, such as heart rate, blood pressure, sphincter function, and digestion. The ANS is divided into three distinct components: the enteric, parasympathetic, and sympathetic nervous systems. The enteric nervous system consists of the myenteric plexus of Auerbach and the submucosal plexus of Meissner, both located in the wall of the alimentary canal. The enteric nervous system interacts with the CNS and parasympathetic and sympathetic components of the ANS but can function entirely independently. It is responsible for sensation and coordination of peristalsis in the gut. Neurons in the enteric nervous system arise from the same progenitors as neurons in the CNS. Hence many neurologic disorders concomitantly affect both the central and enteric nervous systems, including irritable bowel syndrome, anxiety, and depression.[53]

Sympathetic Nervous System

The sympathetic nervous system consists of preganglionic and postganglionic components. Preganglionic fibers originate from neurons in the thoracolumbar region of the spinal cord, giving the sympathetic ANS its anatomic name: the thoracolumbar outflow. Preganglionic fibers exit the spinal cord via the ventral roots with the thoracic and lumbar nerves. After traveling together for a short distance, the preganglionic fibers diverge from the spinal nerves and enter the sympathetic ganglia via the white communicating rami (preganglionic fibers are thinly myelinated; hence, white). The preganglionic fibers carrying output to the head, thorax, and limbs synapse onto neurons in sympathetic ganglia located close to the spinal cord. These ganglia form the paravertebral sympathetic chain that extends from the cervix to the coccyx. The preganglionic fibers carrying output to the abdominal and pelvic viscera synapse onto cells located in sympathetic ganglia farther away from the spinal cord, called the *prevertebral ganglia.* These include the celiac, superior mesenteric, and inferior mesenteric ganglia. Postganglionic neurons from either the paravertebral or prevertebral ganglia send their fibers to the target organs via the gray communicating rami (postganglionic fibers are unmyelinated and hence gray). In the sympathetic ANS, preganglionic neurons use acetylcholine

as a neurotransmitter, whereas postganglionic neurons use norepinephrine at the target organs. The exception is the sweat glands, which receive postganglionic sympathetic fibers using acetylcholine.[40]

The sympathetic ANS generally functions to prepare the body for states of increased energy expenditure. Activation of the sympathetic ANS leads to increased heart rate, decreased peristalsis, redistribution of blood from the gut to the peripheral muscles, and pupillary dilatation (mydriasis). Furthermore, the sympathetic ANS directly innervates the adrenal medulla and, when activated, stimulates the medulla to release norepinephrine and epinephrine into the systemic circulation. Systemic catecholamine release produces relatively global and long-lasting effects. In critical care, a significant component of vasopressor support relies on mimicking the effect of sympathetic ANS activation with exogenously administered epinephrine and norepinephrine.

Although autonomous, the sympathetic nervous system is under significant central control. Interruption of the descending control pathways, such as occurs with spinal cord trauma above the level of T1, results in sudden loss of sympathetic tone, causing profound bradycardia and hypotension. This syndrome, termed *neurogenic* or *spinal shock,* emerges early after injury and requires aggressive pharmacologic intervention in order to minimize secondary insults resulting from hypoperfusion of the injured spinal cord.[54,55]

Parasympathetic Autonomic Nervous System

The preganglionic fibers of the parasympathetic ANS originate in the brainstem and sacral spinal cord. Hence the parasympathetic ANS comprises the craniosacral outflow. The brainstem preganglionic fibers travel along cranial nerves III, VII, IX, and X, while the sacral preganglionic fibers travel with the pelvic splanchnic nerves. Parasympathetic ganglia are located close to their targets, unlike the ganglia in the sympathetic ANS. The parasympathetic ANS, also unlike its sympathetic counterpart, uses acetylcholine as a neurotransmitter both in presynaptic and postganglionic neurons. Target organs for the cranial portion of the parasympathetic ANS include the ciliary muscle and pupillary sphincter, innervated by CNIII via the ciliary ganglion; lacrimal and salivary glands; as well as the majority of thoracic and abdominal organs innervated by the vagus nerve (CNX). The sacral portion innervates the bladder and genitalia.

The parasympathetic system, in general, exerts effects opposite to those of the sympathetic ANS. Thus ACh release from parasympathetic fibers causes bradycardia, hypotension, increased gastrointestinal motility, and pupillary constriction. In critical care, atropine, a competitive antagonist of the muscarinic ACh receptor, is used to prevent or treat bradycardia associated with poor perfusion.[56]

Meninges

The CNS is protected by three membranous layers, which anchor the brain within the skull, contain cerebrospinal fluid (CSF), and form the anatomic basis of the cerebral venous sinuses. From the outside in, these are the dura mater, arachnoid, and pia mater. Dura mater, often simply called dura, is physically the most substantial of the three membranes and is called the *pachymeninx.* The arachnoid and

pia together are referred to as *leptomeninges.* The dura attaches firmly to the inner surface of the skull and arachnoid. Under normal circumstances, no open space exists either between the dura and skull (the epidural space) or between the dura and arachnoid (the subdural space). Under pathologic conditions, however, blood can dissect the epidural and/or the subdural potential spaces to form potentially life-threatening hematomas. The dura's blood supply is provided by the middle meningeal artery, which traverses between the skull and outer dural surface. Trauma to the skull and the middle meningeal artery can lead to an epidural hematoma. The dura also forms the cerebral venous sinuses into which cerebral veins drain. Rupture of the veins as they leave the brain and enter the venous sinuses can lead to a subdural hematoma.

The arachnoid membrane is significantly thinner than the dura, consisting of several cell layers and a spider web–like collagen network. Whereas it adheres to the dura on the outer surface, on the inner surface it is connected to the pia via thin strands of connective tissue called *arachnoid trabeculae.* The space between the arachnoid and pia (subarachnoid space) forms the only true fluid-filled space around the brain, containing CSF, and forming the basis for CSF cisterns throughout the CNS. CSF from the subarachnoid space returns to the venous circulation via special adaptations in the arachnoid membrane called the *arachnoid villi.* Arachnoid villi protrude from the arachnoid into the dural venous sinuses and contain special channels that allow the CSF to flow out of the subarachnoid space into the venous blood. Additionally, cerebral arteries and veins run in the subarachnoid space before diving below the brain surface. Hence injury to these vessels results in subarachnoid hemorrhage.

The pia mater is the most delicate of the three membranes. Unlike the dura and the arachnoid, it follows the surface of the brain, diving into every sulcus and following blood vessels for some distance as they enter the brain. Around these blood vessels, it gives rise to potential perivascular spaces called the *Virchow-Robin spaces* that serve as a significant reservoir of malignant cells in pediatric leukemia and lymphoma, necessitating CNS irradiation and chemoprophylaxis.

Blood-Brain Barrier

Anatomy

Two experiments more than 100 years ago demonstrated conclusively the presence of a physical barrier between circulating blood and the brain. In 1885, Ehrlich injected a dye intravenously to show that the dye failed to stain the brain while staining almost all other internal organs.[57] In 1909, Goldman conducted the reverse experiment, injecting dye into the CSF to show that the dye stained the brain but did not penetrate into the general circulation,[58] although more contemporary studies have demonstrated an organized pathway for extracellular fluid and macromolecular flux from brain to blood via CNS lymphatics (see later). Modern anatomic studies revealed that, actually, three physical barriers separate the blood and the brain: the BBB, established by the endothelial capillary cells in the brain; the blood-CSF barrier (BCSFB), established by cells in the choroid plexus; and finally, the CSF-brain barrier, composed of ependymal cells lining the surface of the ventricles. All three systems shield the brain from changes in ionic and biochemical milieu that

may jeopardize neuronal function, and all three are important for accomplishing drug transport into and out of the brain parenchyma.[59] However, from the standpoint of clinical relevance to pediatric critical care medicine, the subsequent discussion focuses primarily on the BBB and BCSFB.

The cellular component of the BBB in mammals comprises specialized endothelial cells in brain capillaries, pericytes, and foot processes of brain astrocytes, as well as neurons (Fig. 60.4). Endothelial cells in the brain are linked together by tight junctions, which prevent paracellular diffusion of substances from blood into the brain. The endothelial tight junctions in the brain possess extremely high electrical resistance, resulting in the exclusion of even small ions such as K^+ and Na^+.[60] In addition, the absence of fenestrations, high metabolic rate, and low vesicular transport in endothelial cells severely limit transcellular diffusion of water-soluble substances through the cell membrane. Pericytes surround the endothelial cells and display both contractile and phagocytic properties. Their presence likely contributes to the impermeability of the endothelial tight junctions, as well as to blood vessel reactivity[61] and vessel wall elastic properties in the brain.[62] Pericytes in turn are ensheathed by perivascular astrocytes, which extend cellular processes, known as "end-feet," toward the brain vasculature.[60] The astrocytes are critical for the proper development of the brain-specific phenotype of endothelial cells comprising the BBB.[63] Finally, neurons have been shown to innervate the brain capillary endothelial cells directly, although their exact role in BBB function remains unknown.[64]

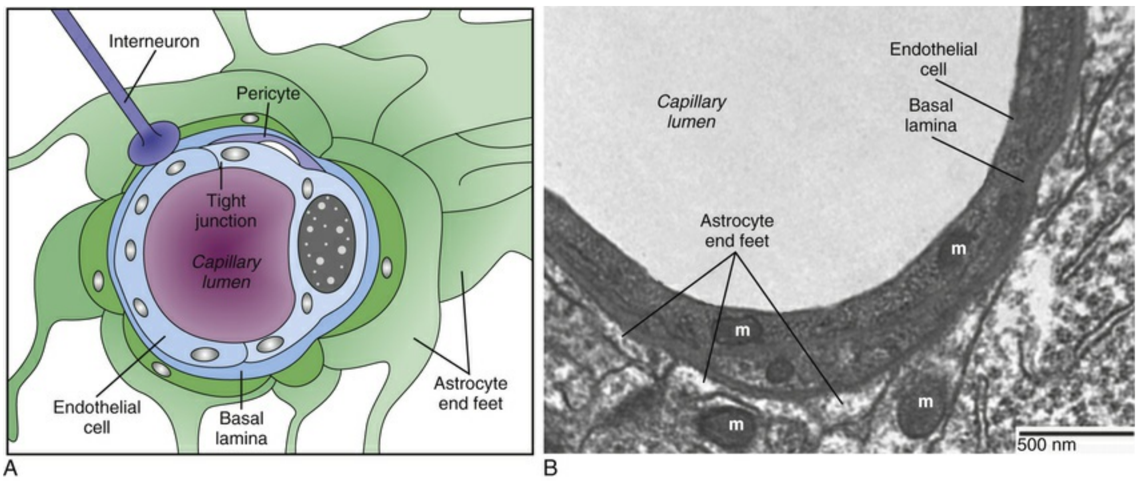

FIG. 60.4 (A) Schematic representation of the major anatomic features contributing to the blood-brain barrier (BBB). It should be noted that endothelial cells surrounding the capillary are linked by tight junctions. (B) An electron micrograph from a mouse brain showing a brain capillary in cross section. The BBB is an active structure, with high energy demands. Hence BBB endothelial cells and astrocytes possess a large number of mitochondria *(m)*.

In addition to the cellular components, the BBB also contains two distinct and important acellular components: the basement membrane and the extracellular matrix. At present, the role of the extracellular matrix in maintaining or establishing the BBB is unknown. The role of the basement membrane, on the other hand, is better characterized. The basement membrane surrounding small draining venules

consists of the endothelial layer, immediately adjacent to the brain capillary endothelium, and the parenchymal layer, which is adjacent to astrocyte end-feet. Interposed between the two basement membranes is a layer of meningeal epithelium. Around the capillaries, however, the meningeal epithelium disappears, and the two layers of the basement membrane fuse to form a composite structure.[60] The basement membrane generally consists of four major types of glycoproteins: collagen type IV, laminin, nidogen, and heparan sulfate proteoglycan. The clinical relevance of these proteins, although not fully understood at this time, is underscored by mutations in collagen type IV that result in intracerebral hemorrhage and porencephaly in rodents and in humans.[65,66]

Selectivity

If the BBB limits the penetration of substances into the CSF, then how is transport of energy sources, signaling molecules, and drugs from blood into the CSF accomplished? Three general transport mechanisms allow chemicals to penetrate from the circulation into the CSF: (1) diffusion of lipid-soluble molecules; (2) receptor-facilitated transport, either energy-dependent or independent; and (3) ion channel-mediated transport. Additionally, several groups of transporters are dedicated to actively pumping substances out of CSF into the circulation.

As a general rule, lipid-soluble substances penetrate into CSF by diffusing across the endothelial plasma membrane, whereas water-soluble substances require active transport to cross the BBB. This property is illustrated by Fig. 60.5, which demonstrates uptake of substances into the brain as a function of their oil-water partition coefficient. Compounds such as benzodiazepines, nicotine, and heroin are highly lipid soluble and penetrate readily into the CSF. The synthetic opiate fentanyl induces the narcotic effect more rapidly than morphine because fentanyl is more lipophilic. The concentration of a lipophilic substance in the CSF is generally directly proportional to its concentration in the plasma. In contrast, mannitol and sodium ions are extremely water soluble, do not penetrate into the CSF across the intact BBB, and are thus used clinically to increase serum osmolality relative to that of CSF and to draw water out of the brain in order to decrease ICP. Lipophilic substances with a significant protein-bound fraction (eg, phenytoin) constitute an exception to the generalization that lipid-solubility and plasma concentration determine CSF concentration. Consequently, in the case of phenytoin and its commonly used prodrug fosphenytoin, therapeutic levels are determined by plasma, or free, concentration, rather than the total concentration, which includes the protein-bound fraction.

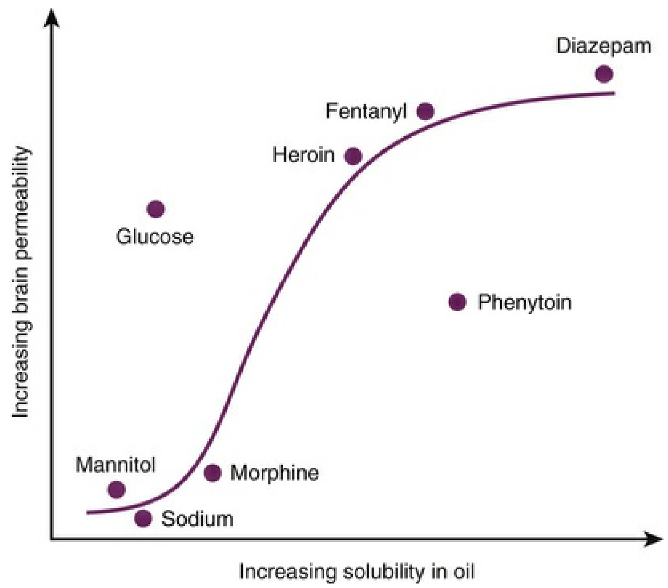

FIG. 60.5 Lipid solubility predicts penetration across the blood-brain barrier *(BBB)*. Substances to the left of the curve, such as glucose, cross the BBB at a higher rate than would be predicted on the basis of their oil solubility. These substances are transported by carriers across the BBB via either an energy-dependent or energy-independent process. In contrast, substances to the right of the curve, such as phenytoin, are highly lipid soluble but are transported across the BBB out of the brain milieu. (Adapted from Laterra J, Goldstein GW. Ventricular organization of cerebrospinal fluid: blood-brain barrier, brain edema, and hydrocephalus. In Kandel ER, Schwartz JH, Jessel TM, editors. Principles of Neural Science. New York: McGraw-Hill; 2000.)

Receptor-facilitated transport across the BBB can be grouped into processes that require energy and those that do not. The best studied and perhaps most clinically relevant example of receptor-facilitated energy-independent transport is delivery of glucose from plasma into the CSF by the GLUT1 transporter. GLUT1 is a 492 amino-acid membrane protein that resides both on the luminal (facing the plasma) and the abluminal (facing the CSF) surfaces of the endothelial plasma membrane.[67] GLUT1 transports glucose down the concentration gradient and can function in a bidirectional manner. The flow of glucose from plasma into the CSF, rather than in the opposite direction, is ensured by (1) higher plasma glucose concentration (≈3 : 2 of CSF); (2) high glucose utilization rate by neurons and glia in the CNS such that glucose delivered into the CSF is exhausted rather quickly; and (3) higher density of GLUT1 transporters on the abluminal surface compared with the luminal surface.[68] In addition, metabolic factors such as hypoxia and ischemia exert transcriptional control over expression and distribution of the GLUT1 transporter, suggesting the existence of tightly controlled mechanisms regulating glucose delivery into the CSF under stressful conditions. Recently, a disorder characterized by GLUT1 deficiency was recognized in a subset of infants with developmental delay, intractable epilepsy, and delayed myelination.[69] Identification of the molecular underpinning of this disorder was driven by the clinical finding of low CSF glucose concentration (hypoglycorrhachia) on repeated lumbar punctures despite normal plasma glucose concentrations in two original patients from the study, highlighting the importance of biochemical BBB function.

While the energy-independent GLUT1 plays an important role in delivering its

substrate down the concentration gradient into the CSF, energy-dependent transporters of the ATP-binding cassette (ABC) family function primarily to pump substances against the concentration gradient out of the CSF into plasma.[70] The ABC family of transporters is divided into seven known groups (A through G), of which groups B, C, and G are highly expressed on BBB endothelial cells. The best-described members of this family include the multidrug resistance (MDR) proteins, such as the P-glycoprotein (PgP), and the multidrug resistance-associated proteins (MRP). Human PgP transports a wide range of chemically and structurally diverse substances out of the CSF, including dexamethasone, phenytoin, ondansetron, and chemotherapeutic agents such as etoposide and vincristine.[70] MRPs also contribute to the ATP-dependent efflux of drugs such as 6-mercaptopurine, methotrexate, and, interestingly, pravastatin. The latter belongs to a class of drugs, hydroxymethylglutaryl-CoA (HMG-CoA) reductase inhibitors, that confers protective effects in experimental models of ischemic and traumatic brain injury[71,72] and reduce stroke risk in humans by approximately 30%, to some extent independent of the reduction in cholesterol levels.[73] Thus increasing the intracerebral levels of HMG-CoA reductase inhibitors via reduction in MRP-dependent efflux may represent a therapeutic strategy aimed at ameliorating the effect of trauma and hypoxia on the brain parenchyma. Indeed, the general strategy of inhibiting MDR and MRP transporters to enhance drug delivery into the CNS is currently being explored in clinical trials.

Blood-Brain Barrier–Deficient Areas

Several areas of the brain have special adaptations in the structure of the BBB that allow the CNS control centers to monitor and interact with the rest of the body. These include the posterior pituitary, the subfornical organ, and the area postrema; in all of these areas, capillaries contain fenestrations, and the BBB is quite leaky. The posterior pituitary contains projections of the hypothalamic vasopressin-containing secretory neurons. When salt concentration increases during volume depletion, these neurons are stimulated to release vasopressin (ADH) directly into the bloodstream, leading to increased water retention in the renal tubules and restoration of intravascular volume. The subfornical organ, located at the foramen of Monro on the ventral surface of the fornix, is also involved in maintaining salt-water homeostasis. Angiotensin II production during states of decreased renal perfusion is detected by neurons in the subfornical organ, which then stimulate vasopressin-containing neurons to release vasopressin and also stimulate neurons in the lateral hypothalamus to create an overwhelming sensation of thirst. Finally, neurons in the area postrema are exposed to toxins circulating in the plasma and stimulate the vomiting reflex. Drugs such as ondansetron are thought to prevent nausea and vomiting by blocking serotonin receptors in the area postrema. All brain regions with a leaky BBB are surrounded by specialized cells called *tanycytes.* Tanycytes are connected by tight junctions that prevent uncontrolled diffusion of substances out of these homeostatic brain regions into the rest of the CSF.

Ventricles and Cerebrospinal Fluid

Ventricular System

The ventricular system arises from the hollow space within the developing neural tube and gives rise to cisterns within the CNS, from the brain to the spinal cord. In the brain, the ventricular system consists of paired lateral ventricles that connect to the midline third ventricle via bilateral foramina of Monro. The third ventricle in turn connects to the fourth ventricle located in the pons and the medulla via the aqueduct of Sylvius. The fourth ventricle terminates caudally in the central spinal canal and continues as a miniscule midline structure through the spinal cord. The ventricles contain the choroid plexus, which produces CSF, and serve as conduits for CSF flow in the CNS. Ventricular walls are lined with ependymal cells, which are connected by tight junctions and constitute a CSF-brain barrier.

Cerebrospinal Fluid Production and Flow

CSF is produced by both the choroid epithelial cells and the brain parenchyma, with each system contributing approximately 50% to new CSF production. CSF produced by the choroid plexus flows directly into the ventricles, whereas CSF produced by the brain parenchyma must cross the ependymal lining to reach the ventricular system. CSF in humans is produced at a rate of 350 μL/min, resulting in total daily CSF production of approximately 500 mL. Daily CSF production rates, when taken in context of the ventricular volume (30 mL in adults) and of the total CSF volume present in the CNS at any given time (130 mL in adults), indicate that CSF circulates out of the ventricular system where it is produced and CSF is continuously reabsorbed.

CSF flows via foramina of Monro out of the lateral ventricles into the third ventricle, and then via the aqueduct of Sylvius into the fourth ventricle. The former two are closed systems, whereas the latter, the fourth ventricle, has three openings that connect the ventricular space with the subarachnoid space. The midline median aperture (foramen of Magendie) and the paired lateral apertures (foramina of Luschka) connect the fourth ventricle with the cisterna magna and the pontine cistern, respectively. Thus out of the fourth ventricle, CSF flows into the subarachnoid space surrounding the brain and the spinal cord. CSF is then reabsorbed by the arachnoid villi into the superior sagittal venous sinus (Fig. 60.6). Knowledge of CSF flow and reabsorption patterns allows for prediction of pathologic findings when either process is interrupted. Obstruction to CSF outflow at any point in the pathway, such as often occurs with tumors, or abnormal CSF reabsorption, such as seen in meningitis or hemorrhage due to cellular debris blocking the arachnoid villi, results in intraventricular CSF accumulation and hydrocephalus. Hydrocephalus may then lead to increased ICP and cerebral herniation, either spontaneous or iatrogenic, for example when a lumbar puncture is performed on a patient with obstruction above the level of the foramen magnum.

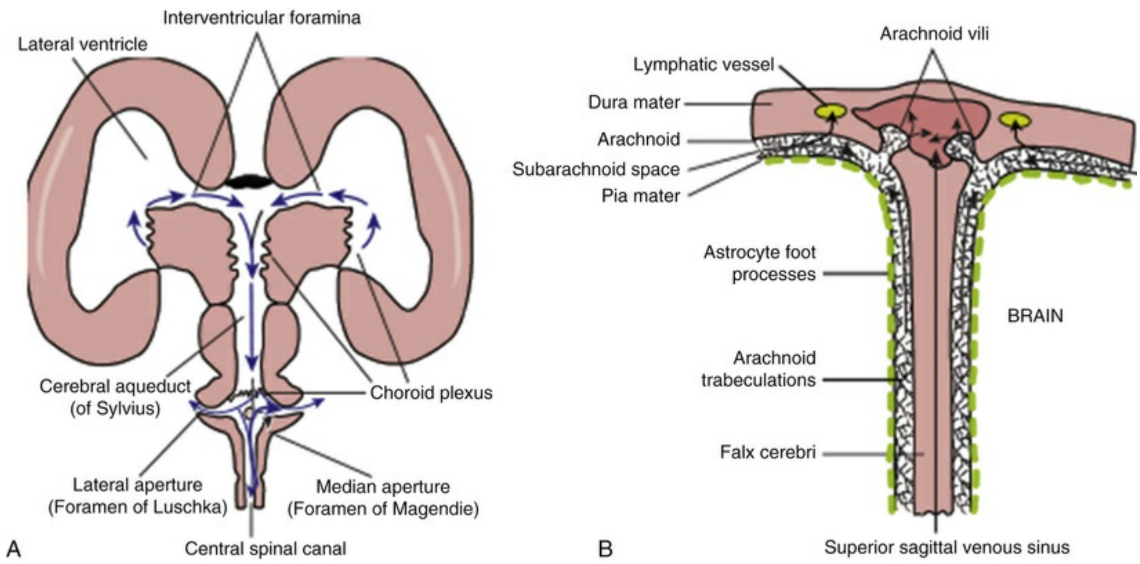

FIG. 60.6 The ventricles and cerebrospinal fluid (CSF) flow. (A) Flow of CSF from choroid plexus through the ventricular system into the subarachnoid space. Note that a portion of the CSF circulating into the distal spinal cord returns to the fourth ventricle. (B) Schematic representation of CSF absorption from the subarachnoid space into the cerebral venous sinus system and perivenous lymphatic vessels.

Cerebrospinal Fluid Composition and Function

Cells in the choroid plexus actively secrete CSF from the plasma that filters through leaky choroid plexus capillaries. The process is controlled by multiple mechanisms, resulting in CSF ionic, chemical, and cellular composition that is distinct from blood and plasma. In general, CSF contains higher magnesium and chloride concentrations and lower potassium and calcium concentrations compared with plasma. Glucose concentrations in CSF are approximately two-thirds of plasma levels. CSF has very few cells and a constant protein level. As is well known, these constituents are disrupted in disease. In bacterial meningitis, glucose concentrations are lower than expected and protein concentration is increased. In contrast, in viral meningitis, CSF glucose is usually normal while protein concentration is increased. More recently, levels of various cytokines and proteins leaked from neurons and myelin sheaths have been explored as potential biomarkers of the severity and type of brain injury.[74]

The primary purpose of the CSF is to provide a supportive buoyant environment for the brain. The human brain has the consistency of an incompletely hardened bowl of gelatin. Without the CSF, the human brain flattens significantly under the force of gravity, whereas, suspended in CSF, it retains its native shape. Furthermore, CSF provides a fluid cushion against acceleration-deceleration insults that may be delivered to the brain by the surrounding skull. CSF also functions both as a source of nutrients and a relatively large-volume sink for waste and toxic substances produced in the course of normal neuronal activity. For instance, excess glutamate released at the synapse rapidly diffuses into the CSF, minimizing potential excitotoxicity to both presynaptic and postsynaptic neurons. Excess magnesium ions in the CSF may also participate in the Mg^{2+} block at the NMDA receptors (see section on glutamate receptors), allowing for coincidence detection and learning.

Vasculature in the Central Nervous System

Brain Vasculature

The arterial blood supply to the brain is traditionally divided into an anterior portion supplied by the paired internal carotid arteries and the posterior portion supplied by the paired vertebral arteries. The anterior and posterior arterial circulations are interconnected at the base of the brain via circle of Willis.

The internal carotid artery originates from the common carotid artery at approximately the level of angle of the jaw in humans. It enters the skull through the carotid canal anterior to the jugular foramen, takes a relatively standard but tortuous course through the temporal bone and the cavernous sinus, and then enters the dura mater above the sinus, running horizontally inferolateral to the optic nerve. At this point, it gives off the ophthalmic artery and, a short distance later, the anterior choroidal artery and posterior communicating artery. The former supplies several clinically relevant structures, including parts of the thalamus, hippocampus, optic tract, and internal capsule. The latter, the posterior communicating artery, forms part of the circle of Willis and connects the anterior internal carotid circulation with the posterior vertebral circulation. After generating the posterior communicating artery, the internal carotid bifurcates into major vessels supplying the brain: the anterior and middle cerebral arteries (ACA and MCA, respectively).

The bilateral ACAs connect via the anterior communicating artery at the circle of Willis. Both ACAs then run along the medial surface of the brain and supply the corpus callosum and the medial portions of the cerebral cortex on their respective sides, extending up to and including the postcentral gyrus. Thus ACA occlusion results in damage (among other areas) to the medial portions of the primary sensory and motor cortices, which correspond to the more caudal parts of the human body, such as legs, trunk, and shoulders.

While the ACA supplies blood to the medial cerebral cortex, the MCA provides blood flow to almost the entire lateral portion of the cortex. After diverging from the internal carotid artery, the MCA dives deep into the Sylvian fissure, where it supplies the insula. In addition, within the Sylvian fissure, the MCA gives off small lenticulostriate arteries that supply the thalamus and basal ganglia. The MCA then emerges from the Sylvian fissure and divides into multiple branches responsible for nourishing the lateral components of the frontal, temporal, and parietal lobes. MCA occlusion secondary to ischemic stroke generally results in devastating neurologic deficits. Additionally, in cases of globally decreased perfusion such as seen during cardiac arrest or prolonged hypotension, the border (watershed) zone between the cortical areas supplied by the ACA and the MCA tends to be vulnerable to early injury.

The posterior circulation arises from the paired vertebral arteries, each of which gives rise to a posterior inferior cerebellar artery (PICA) before coalescing into a single basilar artery at the level of the junction between the medulla and the pons. The PICAs supply the inferior portion of the cerebellum, as well as the choroid plexus in the fourth ventricle and the lateral medulla. The basilar artery proceeds rostrally and gives rise to the paired anterior inferior cerebellar and superior cerebellar arteries (AICA and SCA, respectively). At the level of the midbrain, the basilar artery bifurcates into the posterior cerebral arteries (PCA), which supply the

occipital lobes and portions of the temporal lobes. In addition, the PCAs nourish a number of thalamic sensory nuclei. Each PCA is connected to the ipsilateral internal carotid artery by the posterior communicating artery. Since the PCA supplies the areas of the thalamus concerned with sensation and cortical areas dedicated to vision, PCA occlusion often results in sensory and/or visual loss on the side contralateral to injury.

Spinal Cord Vasculature

The spinal cord is supplied by two interconnected arterial systems: the longitudinal vasculature that arises from the vertebral arteries and the segmental vasculature that arises from multiple levels along the vertebral arteries and the aorta. The longitudinal arteries consist of a single anterior spinal artery and paired posterior spinal arteries. The anterior spinal artery runs along the anterior median fissure and supplies the ventral two thirds of the spinal cord. Occlusion of the anterior spinal artery, which can occur with traumatic dissection or autoimmune arteritis, results in the anterior spinal syndrome, or Beck syndrome. Beck syndrome is characterized by symmetric weakness and loss of temperature and pain sensation with relative sparing of vibration and position sensation below the level of injury. The paired posterior spinal arteries run along the dorsal columns and supply blood to the posterior one-third of the spinal cord, which includes the dorsal columns and most of the dorsal horns. Posterior spinal arteries are extensively interconnected and receive blood supply from multiple segmental arteries along their course. Thus isolated lesions due to posterior spinal artery occlusion are rare.

The segmental arterial blood supply to the cervical spinal cord arises from the vertebral arteries via the radicular arteries, whereas that to the thoracic and lumbar spinal cord arises from the aorta via the thoracic intercostal arteries and lumbar arteries. Both thoracic and lumbar segmental arteries give rise to smaller radicular arteries that penetrate the intervertebral foramina and supply the spinal cord. In addition, the lower thoracic aorta often gives rise to a single great radicular artery (artery of Adamkiewicz) that supplies the entire lower two-thirds of the spinal column. The artery of Adamkiewicz is often the sole source of blood flow to the lower thoracic spinal cord during surgical repair of coarctation of the aorta. Thus care is taken to ensure adequate distal perfusion pressure during cross-clamp to minimize the risk of paraplegia. In general, spinal cord watershed areas exist at the upper thoracic (T1-T4) and upper lumbar (L1) levels, where interconnections among the segmental arteries are less developed. At any given level, the interior portion of the spinal cord is most susceptible to hypoxic-ischemic injury. For example, in cases of severe cervical hyperextension, hypoxic and/or vascular injury to the central portion of the cervical spinal cord results in central cord syndrome, characterized by muscle weakness in upper extremities to a greater extent than in lower extremities, by urinary retention, and by variable degree of sensory loss.

Regulation of Cerebral Blood Flow

In healthy mammals, the perfusion of cerebral tissues is exquisitely controlled. Blood flow to the brain, as to many other vital organs, is autoregulated by homeostatic mechanisms designed to maintain adequate perfusion. Cerebral autoregulation

occurs on the basis of three primary mechanisms: perfusion pressure–based autoregulation, pH-based (PCO_2-based) autoregulation, and metabolic coupling. All three play a major role in determining cerebral blood flow (CBF) in health and in disease, such as trauma and hypoxia-ischemia.

Perfusion Pressure–Related Autoregulation

Experiments in the mid-20th century demonstrated that normal CBF in young adults is 50 to 55 mL/100 g brain/minute, resulting in approximately 750 mL/min total CBF.[75] Thus under resting conditions, the brain receives approximately 15% of total cardiac output. In children, CBF is generally higher than in adults, on the order of 100 mL/100 g brain/min for an 8-year-old child.[76] CBF is kept relatively constant over a range of mean arterial blood pressures (MAPs) by continuous adjustment of vascular tone in brain arterioles (Fig. 60.7A). In adults, CBF remains essentially invariant while MAP is between 50 and 150 mm Hg. Also in adults, CBF decreases and increases passively as a function of MAP when MAP is below 50 or above 150 mm Hg, respectively. The pressure-dependent autoregulatory range is different in newborns, with important clinical implications. The lower limit of autoregulation in neonates appears similar to that in adults at approximately 40 mm Hg; the upper limit, however, is much lower for infants than adults, with CBF increasing linearly as a function of MAP greater than 90 mm Hg.[77] Because infants have an MAP that is much closer to the lower limit of CBF autoregulation, even moderate hypotension in young children may severely impede oxygen delivery to the brain. Similarly, at the upper limit, moderate hypertension may result in unacceptable increases in CBF and damage to the BBB. One of the many clinical applications of this principle is the need for meticulous control of MAP in infants on cardiopulmonary bypass in order to minimize the risk of intracranial hemorrhage.

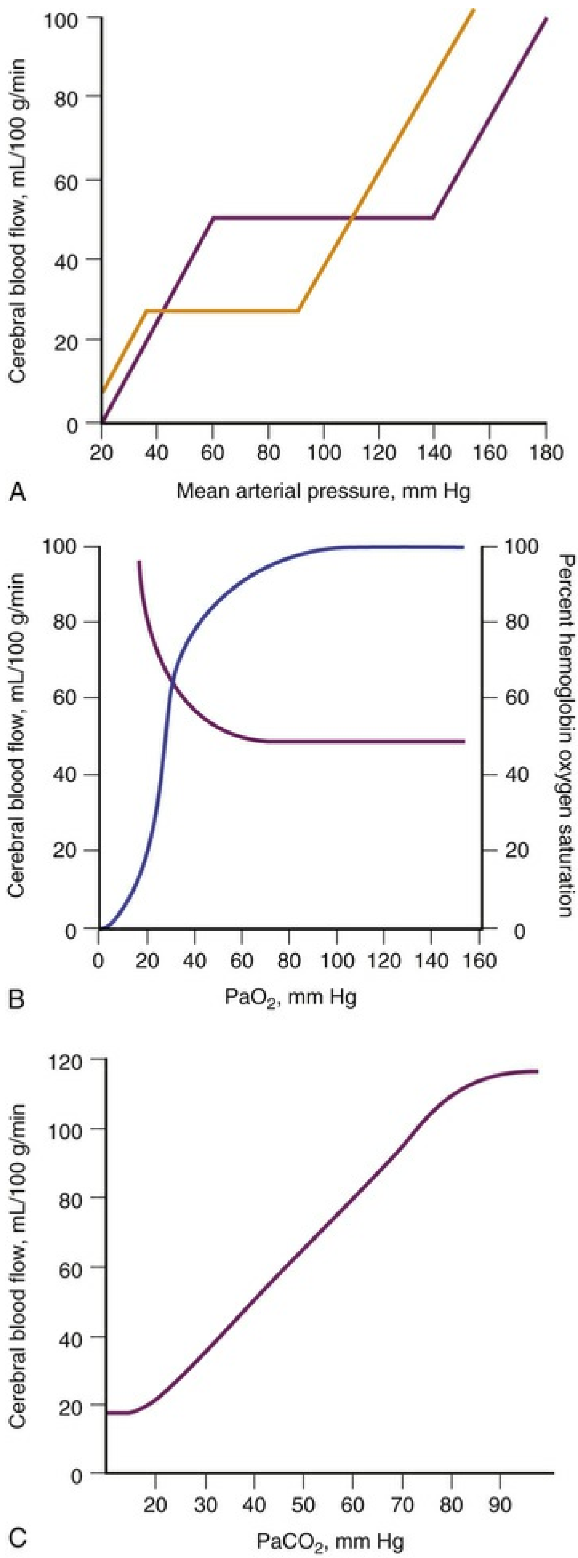

FIG. 60.7 Regulation of cerebral blood flow (CBF). (A) Blood pressure–dependent autoregulation, adult *(red curve)* and infant *(orange curve)*. (B) Oxygen-dependent regulation. *Red curve,* CBF (left ordinate); *blue curve,* hemoglobin-oxygen saturation curve (right ordinate). Note that CBF begins to increase at the PaO_2, at which hemoglobin oxygen saturation begins to decrease. Since oxygen delivery is determined by hemoglobin oxygen saturation to a much larger extent than by PaO_2 and dissolved oxygen in the blood, CBF in humans increases in response to decreasing

oxygen delivery, which in turn is correlated with decreasing PaO_2. (C) $PaCO_2$-dependent regulation CBF should increase linearly with $PaCO_2$ except at the extremes of the physiologic range.

Oxygen-Related Autoregulation

CBF generally remains constant while PaO_2 remains over 60 mm Hg. When PaO_2 decreases below this threshold value, CBF increases almost exponentially as a function of PaO_2 (Fig. 60.7B). Several distinct pathways contribute mechanistically to oxygen-related regulation of CBF, including hydrogen and potassium ions, nitric oxide, arachidonic acid, adenosine, and ATP-sensitive potassium channels.[78,79] The shape of the PaO_2-CBF curve is explained by the hemoglobin-oxygen dissociation curve and the fact that, in humans, CBF depends on blood oxygen content and not on PaO_2.[80] When PaO_2 is less than 60 mm Hg, the percentage of oxyhemoglobin decreases sharply, significantly decreasing the blood oxygen content. CBF rises as a consequence of decreased oxygen delivery. Conversely, increasing PaO_2 above 60 mm Hg does not significantly increase blood oxygen content since hemoglobin is more than 90% saturated with oxygen at these partial pressures. Hence in healthy people, CBF remains constant once PaO_2 crosses the threshold of 60 mm Hg.[81] Furthermore, when inspired oxygen fraction is increased further from 21% to 100%, CBF actually decreases by approximately 15% to 20%.[80] Both hypoxia-related vasodilatation and hyperoxia-related vasoconstriction may be impaired under pathologic conditions such as traumatic brain injury and may portend a poorer outcome. Nevertheless, a PaO_2 less than 60 mm Hg should be rigorously avoided in patients with increased ICP lest hypoxia-related vasodilatation further contribute to decreased compliance within the cranial vault.

Hydrogen Ion–Related Autoregulation

CBF is directly proportional to perivascular pH and, therefore, inversely proportional to the perivascular hydrogen ion concentration. In clinical practice, this relation translates into dependence of CBF on $PaCO_2$ because $PaCO_2$ is related to pH via the bicarbonate buffer system. Within a $PaCO_2$ range from 20 to 100 mm Hg, CBF increases by 2.5% to 4% for every 1 mm Hg increase in $PaCO_2$.[82] No further changes in CBF are observed when $PaCO_2$ is either below 20 mm Hg or above 100 mm Hg (Fig. 60.7C). The observed change in CBF in response to change in $PaCO_2$ is relatively transient, lasting hours. Restoration of intracerebral bicarbonate concentration is thought to be responsible for the temporary nature of the CBF response. Therefore once the brain and CBF have been “reset” to a new $PaCO_2$, acutely restoring $PaCO_2$ into a physiologically normal range actually results in disruption of the acid-base balance in the brain and may exacerbate injury. As such, chronic hyperventilation is not recommended as a therapy for increased ICP. Nevertheless, hyperventilation with concomitant rapid reduction in $PaCO_2$ remains one of the acute treatments for life-threatening increases in ICP and impending brain herniation.

Metabolic Coupling

Local CBF is coupled to the metabolic tissue demands in a relatively small, circumscribed area, reflecting both neuron- and astrocyte-specific energy needs. At rest, areas with greater energy needs, such as the gray matter, receive a greater proportion of CBF than areas with lesser energy needs, such as the white matter. The metabolic rate can be expressed as either cerebral metabolic rate of glucose (CMRGlu) or cerebral metabolic rate of oxygen ($CMRO_2$). Both CMRGlu and $CMRO_2$ have been correlated with CBF. Under conditions of sensory stimulation, however, the increase in CBF to the cortical sensory areas exceeds the increase in $CMRO_2$, suggesting that neuronal activity itself can influence CBF independent of the metabolic demand.[83] Neuronal activity–dependent increases in CBF form the presumed basis of functional magnetic resonance imaging, allowing for detailed studies of brain processes in humans.[84] In children, $CMRO_2$ increases until about 14 years of age and then decreases to adult values.[85] Similarly, CMRGlu increases from infancy until around 9 years of age and then decreases until adulthood.[86] The relationship between disturbances in metabolic coupling of CBF and injury is unclear at this time, although emerging evidence indicates occurrence of metabolic crises in the brain after traumatic injury and cardiac arrest.[76] Whether these crises reflect abnormal CBF regulation and predict outcome remains under investigation.

Emerging Characterization of the “Lymphatic” Circulation in the CNS

Until recently, the CNS has been unique among mammalian organ systems in its supposed absence of a dedicated lymphatic system for regulation of interstitial fluid composition and waste removal. Reexamination of old data and increasing abundance of new data indicate, however, that the mammalian CNS is endowed with a robust two-part lymphatic system—traditional lymphatic system along the dural venous sinuses and a unique “glymphatic” system in the brain parenchyma.

Early studies in multiple mammalian species demonstrated that up to 50% of brain interstitial fluid drains through deep cervical lymph nodes. Injection of radioactive and other tracers into the brain parenchyma resulted in preferential labeling of retropharyngeal lymph nodes.[87] Estimates of draining kinetics suggested that CSF flow through the ventricles into the cisterna magna accounted for less than 20% of total tracer clearance from the brain.[88] In 1981, Cserr and colleagues[88] presciently suggested that proteins in the brain parenchyma are cleared via bulk flow through the perivascular spaces into the deep cervical lymph nodes. These early findings were essentially forgotten for 30 years until discovery of lymphatic vessels in the CNS and rediscovery of bulk interstitial fluid flow along perivascular spaces in the 21st century.

Discovery of lymphatic vessels in the dural venous sinuses occurred during a search for a gateway that allows peripheral T cells to enter and exit the CNS during routine immunologic surveillance and during states of acute inflammation.[89] A novel preparation of mouse meninges revealed an unexpected linear arrangement of T cells in vessel-like structures. These vessel-like structures run along the dural venous sinuses and consist of cells with many immunologic markers of lymphatic

endothelial cells. Unlike the systemic lymphatics, however, CNS lymphatic vessels do not contain smooth muscle cells or intraluminal valves. Fluorescent tracers injected into the cerebral ventricles, but not those injected into the systemic circulation, fill these vessels, demonstrating that CNS lymphatic vessels drain CSF. CSF flow in these vessels has a rate and direction similar to those of blood flowing in the venous sinuses.[89] Major drainage occurs via several routes—along the middle meningeal and pterygopalatine arteries, internal jugular veins, and cranial nerves and into nasal mucosa through the cribriform plate.[90] Ultimately, CNS lymphatic vessels appear to drain into deep cervical nodes.

Flow of CSF into the CNS lymphatic vessels occurs at least in part through a "glymphatic" system in the brain parenchyma (Fig. 60.6B). The glymphatic system, so called because of the crucial role of glia in its function, was rediscovered during a search for an answer to a specific question: How does the brain get rid of waste extracellular proteins? To answer this question, Nedergaard and colleagues[91] injected a fluorescent tracer into the cisterna magna of anesthetized mice and imaged its flow through the subarachnoid space using in vivo microscopy techniques. The tracer rapidly diffused throughout the subarachnoid space and then entered the brain parenchyma along the paravascular space, which accompanies the deep penetrating arterioles in the brain. This potential paravascular space has been known to exist for more than 100 years from anatomic and pathologic studies and is called a Virchow-Robin space. Bulk CSF flow along Virchow-Robin spaces occurred with arterial pulsations. Tracers of small molecular size diffused into the brain parenchyma and with time began to accumulate along small venules, ultimately reaching the larger cerebral veins. These experiments demonstrated that CSF circulates from subarachnoid space into Virchow-Robin spaces, crosses the brain parenchyma where it mixes with the interstitial fluid, and exits the brain via paravenous spaces to drain into the cerebral veins.

Remarkably, tracers of large molecular size remained in the Virchow-Robin space. They were trapped between the walls of the arterioles and the perivascular end-feet of astrocytes (hence "glymphatic"). Indeed, astrocyte end-feet cover most of the cerebral microvasculature, with ~20-nm clefts between the end-feet.[92] Astrocytes thus filter macromolecules from the CSF flowing into the brain parenchyma. Decreased oncotic pressure of incoming CSF allows inflow of waste molecules, including proteins, from the interstitial fluid and facilitates waste removal from the brain. In addition, the astrocyte end-feet are enriched for the water channel aquaporin-4 (AQP4).[91] AQP4 preferentially allows free water from the CSF in the Virchow-Robin spaces to enter the interstitial space, further facilitating CSF flow and waste excretion.[91] This "rediscovery" of an anatomic-physiologic means for removal of waste and potentially toxic macromolecules from brain has implications in multiple CNS diseases, including traumatic brain injury, stroke, and inflammatory conditions. Furthermore, it provides a portal for brain-derived biomarkers to be accessible in serum.[93]

Developmental Processes Relevant to Pediatric Critical Care Medicine

Cell Origin and Differentiation

Neurogenesis and gliogenesis in the human begin well before birth, in the eighth gestational week.[94] Neurons are born in the specialized proliferative zones located next to the lateral ventricles and migrate outwards toward the cortical surface during development. The neurons migrate along a subset of glial cells called the radial glia, which span the distance between the ventricular zone and the brain surface early in development. The cortex is generated in an inside-out fashion, such that the deeper cortical layers are formed first. Glutamatergic neurons appear to originate in the dorsal aspect of the ventricular zone, whereas GABA-ergic inhibitory interneurons likely come primarily from the ventral aspect. Thus GABA-ergic neurons have a longer migration path into the cortex than their glutamatergic counterparts and occasionally must migrate tangentially rather than perpendicular to reach their final destination.[94] The process of establishing cortical layers appears complete in humans by the 30th gestational week.[95] Disruption of the radial migration process, due to either genetic or environmental factors, results in lissencephaly and seizures of varying severity.[96]

Synaptogenesis and Synaptic Pruning

By the time of birth in humans, both neurogenesis and neuronal migration have essentially been completed. Thus infants generally have the same neuronal density (number of soma per mm^3) as adults. Yet the human brain undergoes substantial postnatal development, reflected clinically as the maturation of behavioral milestones. The underlying process is evolution of axonal and dendritic processes by neurons in the CNS, together with an explosive increase in the number of synaptic contacts in the brain (Fig. 60.8). Neuronal dendritic arbors increase in complexity, developing more branches and sampling a wider physical space during the first 2 years of life.[40] The number of synapses increases from birth until approximately 2 years of age, when it actually surpasses the number of synapses found in the adult brain. From 2 years until early adolescence, neurons in the CNS undergo synaptic pruning, or elimination. Both synaptic development and pruning are under exquisite control by genetic and experience-dependent factors. For example, a major CNS abnormality found in individuals with fragile X syndrome, the most common cause of mental retardation, is overproduction and impaired pruning of synapses in cortical neurons.[97] Furthermore, a number of drugs used extensively in the PICU, including benzodiazepines, barbiturates, steroids, and opiates, exert a profound effect on synaptogenesis and synaptic function. Steroid use in premature neonates has been associated with worse neurologic outcome,[98] and benzodiazepine use during experience-dependent critical periods in the visual system is associated with premature decline in synaptic plasticity.[99] Thus the true extent of the interaction between the PICU environment and synaptic organization in the developing brain remains to be fully characterized.

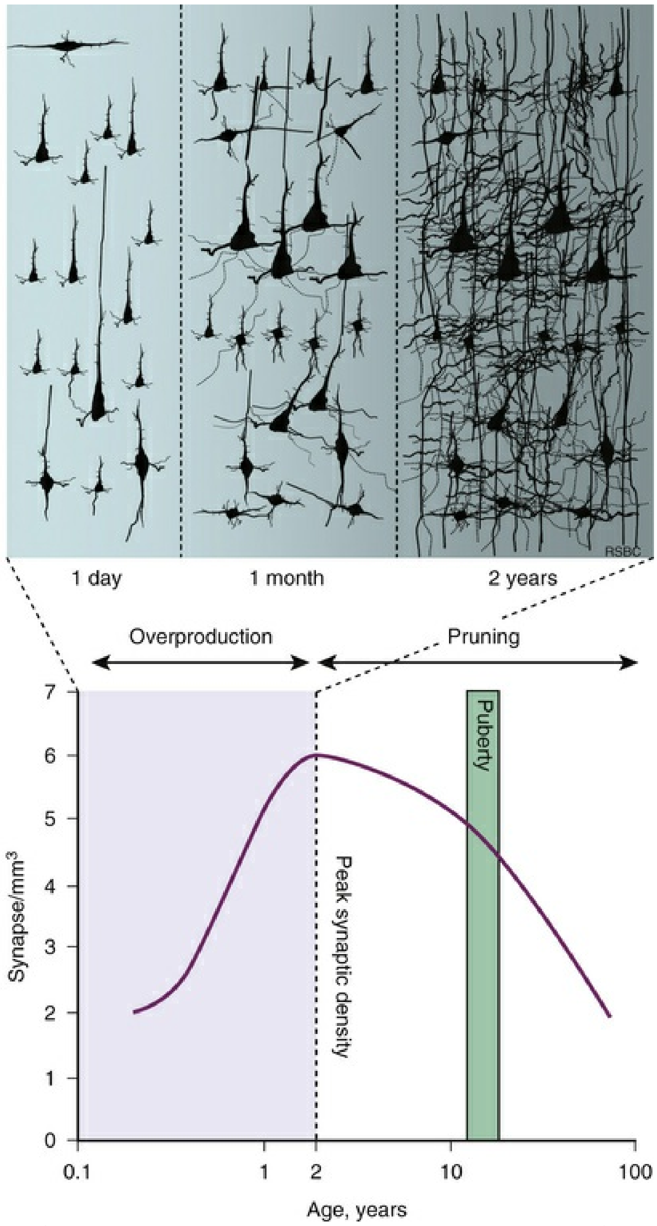

FIG. 60.8 Cortical synaptic density and development of axons and dendrites with age. The synapse density is derived from the visual cortex. Note the logarithmic age scale as abscissa. *Top panel* is a schematic representation of synaptogenesis and dendritic arborization and maturation from birth to 2 years of age. (Modified from Levitt P. Structural and functional maturation of the developing primate brain. J Pediatr. 2003;143:S35-S45 and Nolte J. The Human Brain. An Introduction to Its Functional Anatomy. 3rd ed. St. Louis: Mosby–Year Book; 1993.)

Neurotransmitter System Maturation

Maturation of the neurotransmitter systems in the human CNS is a complicated and protracted process. It is complicated because each neurotransmitter system matures along its own developmental time course and because the time course itself may be specific to each brain region. For some neurotransmitters, the process lasts into early adulthood. The complexity of the process is compounded further by the relative lack of human data, requiring extrapolation from animal studies. Nevertheless, some

general principles that apply to critically ill children can be derived from current knowledge.

The earliest neurotransmitter system to become apparent in the cortex is ACh. Thalamic afferent fibers contain AChE, and ACh staining in the cortex coincides with arrival of thalamic input during midgestation.[94,95] Cholinergic innervation in the cortex continues to mature through the third year of life. Development of the GABA-ergic system also begins in midgestation and continues until several months postnatally. GABA receptor α subunits expressed in cortex before birth differ from those expressed after birth.[100] Indeed, in young animals and probably in humans before late gestation, GABA is an excitatory neurotransmitter, evoking large depolarizing currents in postsynaptic neurons.[101] The precise significance of GABA as an excitatory neurotransmitter in guiding organization of neuronal circuits remains to be determined. Development of the glutamatergic system occurs slightly later, with AMPA-type receptors becoming apparent in the basal ganglia in the 32nd postnatal week. In the cortex, NMDA-type receptors precede the AMPA-type receptors in the course of their appearance at the synapse. Because NMDA receptors do not evoke fast depolarizations leading to an action potential, NMDA-only synapses are functionally silent. Yet these silent synapses contribute to experience-dependent plasticity and possibly injury.[102]

Myelination

Myelination in the human CNS begins 1 to 2 months before birth in the visual system and extends to the other sensory systems over the first year of life.[103] Further myelination of subcortical and cortical tracts continues in the posterior to anterior direction well into the third decade of life, consistent with the time course of maturation of cognitive functions in children and adolescents.[94] Myelination is initiated by the preoligodendrocytes, which are exquisitely sensitive to injury by hypoxia and inflammation. Oligodendrocyte injury, with resulting disruption in axonal myelination, contributes significantly to the development of periventricular leukomalacia in preterm infants.[104]

Development of Cerebrovasculature and Blood-Brain Barrier

Vascularization of the brain begins early during development, with the first vascular plexus surrounding the primitive neural tube before the first heartbeat. Blood vessels then invade the developing brain, growing radially from the pia toward the deeper structures. The process is driven, at least in part, by oxygen sensing. Deeper cortical layers/structures are thought to be relatively oxygen deficient.[105] Relative hypoxia leads to transcription of the hypoxia-inducible factor 1 (HIF1), which in turn leads to release of the vascular endothelial growth factor (VEGF). VEGF drives angiogenesis in the brain both prenatally and postnatally. Interestingly, chronic hypoxia such as is seen in patients with cyanotic heart disease increases the capillary density in the brain via an HIF1-dependent mechanism.[106] The increase is reversed over several weeks by restoring normal oxygenation in animal models, suggesting that brain vasculature has the potential to undergo continuous remodeling.

Development of the BBB coincides with early vascularization of the brain.

Immunologic markers of tight junctions redistribute from the cytoplasm to their appropriate locations in the cell membrane by approximately 14 weeks of gestation.[107] Although anatomically intact, the BBB remains more permeable to amino acids, some drugs, and possibly toxins until approximately 6 months of age in humans.[107] However, the exact nature of BBB dynamics during development remains incompletely characterized.

Developmental Aspects of Cerebral Blood Flow, Autoregulation, and Cerebral Metabolism

In humans, gray matter CBF increases several-fold early in development and then decreases gradually after puberty (Fig. 60.9). In normotensive preterm infants, CBF has been measured at 13 to 14 mL/100 g/min.[108] Estimated CBF increases with gestational age from 14 mL/100 g/min at 30 to 32 weeks to 20 mL/100 g/min at 38 to 40 weeks postconception.[109] Furthermore, CBF increases significantly in the first 2 days of life, regardless of gestational age.[110] In children aged 4 to 12 years, gray matter CBF reaches values of 90 to 100 mL/100 g/min and then declines throughout adolescence to reach adult values of 50 to 60 mL/100 g/min by approximately 20 years of age.[111] Interestingly, white matter CBF is only 20% higher in children compared with adults, reflecting perhaps the greater degree of developmental changes in gray versus white matter.[111]

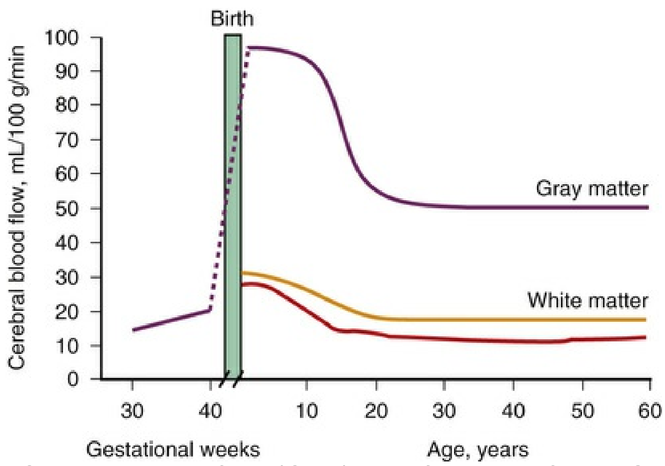

FIG. 60.9 Cerebral blood flow (CBF) as a function of age. Gray matter CBF increases significantly after birth to reach a peak at approximately 4 years of age (note the change from age in gestational weeks to age in years). The *broken line* between the neonatal period and childhood indicates that data are extrapolated from existing experimental data. Gray matter CBF then decreases gradually to adult values. White matter CBF also decreases between 4 years of age and adulthood but not as significantly as that in gray matter. At present, no data exist on the white matter CBF in premature or term newborns.

Perfusion pressure–related, $PaCO_2$-related, and PaO_2-related autoregulation of CBF also undergo postnatal maturation. Studies in preterm infants suggest that perfusion pressure–related autoregulation of CBF is present shortly after birth, such that CBF changes by less than 1.5% per 1 mm Hg change in MAP.[112] As mentioned

earlier, the upper and lower MAP limits in pressure-related autoregulation in neonates are shifted to the right, compared with adults,[77] leading to different thresholds for intervention in infants. Pressure-related autoregulation may be lost in critically ill infants, resulting in pressure-passive CBF[1] and poor outcome.[113] Similarly, $PaCO_2$-related autoregulation appears present in humans shortly after birth, with CBF changing approximately 1% for every 1 mm Hg change in $PaCO_2$.[108,110,114] In preterm infants, CBF also depends on the interaction between $PaCO_2$-related and MAP-related autoregulation, such that the percent change in CBF as a function of change in $PaCO_2$ increases as MAP increases.[114] Finally, oxygen tension-related CBF autoregulation also appears functional early in life, although much of the current data are derived from animals studies.[115,116] Thus in healthy humans, CBF autoregulation mechanisms are functional at birth and should be taken into account during management of systemic and intracerebral pathologic states, such as sepsis, hypotension, hypoxemia, and hypercarbia.

Cerebral metabolism undergoes substantial maturation during postnatal development in humans with respect to metabolic rate, distribution of metabolic activity, and energy source utilization. Shortly after birth, the CMRGlu is highest in sensory and motor cortices, thalamus, and brainstem.[117] Over the next 4 years, CMRGlu increases substantially in the thalamus and in the cortex but remains essentially stable in the brainstem. Cortical areas experiencing the most significant increase in CMRGlu during the first 4 years of life include the frontal, temporal, and occipital regions.[117] Between 4 and 9 years of age, CMRGlu in the cortex remains at consistently high values relative to adults, declining to adult levels by approximately 20 years of age.[86]

In addition to relying on glucose as a substrate, the developing brain also extensively utilizes ketone bodies as an energy substrate. Ketone utilization peaks during the period of maternal milk ingestion, accompanied by an increase in expression of monocarboxylate transporters in the BBB, that facilitate ketone entrance into the CNS.[118,119] Although reliance on ketones as an energy source declines in the CNS with age, recent evidence indicates that ketone production and utilization may play a significant role during times of injury and stress even in an adult brain.[118]

New Insights in Neurodevelopment Relevant to Pediatric Critical Care

Excitatory Amino Acid Inhibition and Neurodevelopmental Apoptosis

There is now widespread acceptance that exposure to NMDA antagonists including inhaled anesthetics, barbiturates, benzodiazepines, and ketamine at key periods during development leads to neurodegeneration in the mammalian brain.[120] In humans and nonhuman primates this is considered to be the third trimester, and in rodents it is up to postnatal day 7. This is thought to be related to exaggerated culling of inhibited neurons—akin to “disuse atrophy,” during critical neurodevelopmental stages, and is the basis for neurologic morbidity observed in

fetal alcohol syndrome.[121] Whether this phenomenon translates to use of sedatives, anesthetics, and/or anxiolytics in infants in the PICU (and especially those born prematurely) remains unclear, although recent data from studies evaluating cognitive consequences of anesthesia for early childhood surgery suggest caution is in order.[122,123]

The Microbiome and Neurodevelopment and Function

Host microbiota and the impact of medical and/or dietary manipulation thereof is emerging as an important aspect of critical illness. Of relevance to this chapter, recent data show that host microbiota regulate maturation and function of CNS microglia.[124] Microglia play key roles in neuronal migration and survival in the developing[125] and adult brain.[126] Microglia can also limit neuronal hyperexcitability by intercalating processes between synaptic clefts[127] and thus may affect neurotransmission in neuroinflammatory conditions such as encephalitis, autoimmune encephalopathies, septic encephalopathy, and traumatic brain injury. In addition to effects on inflammatory cells, gut microbiota can directly influence brain levels of neurotransmitters including GABA and glutamate.[128] Food for thought.

Conclusion

The nervous system is undergoing active development and is often the primarily affected organ when children are hospitalized with a life-threatening illness. Appreciation of normal anatomy and development, as well as knowledge of neurotransmitter systems and homeostatic mechanisms, is required for prompt diagnosis and effective clinical care. Most importantly, ongoing research into the interaction between developmental processes and injury is likely to yield a wealth of new information, implying the need for continuous reevaluation of current knowledge and clinical practice in light of new discoveries.

CHAPTER 61

Brain Malformations

Robert H. Bonow, Isaac Josh Abecassis, Samuel R. Browd

PEARLS

- Hydrocephalus is a common brain disease characterized by a buildup of cerebrospinal fluid that requires surgical treatment. Untreated hydrocephalus can be a medical emergency, requiring prompt neurosurgical intervention.
- Arachnoid cysts are generally benign congenital malformations that are frequently identified incidentally; however, they may occasionally hemorrhage or cause mass effect on the brain. They are more likely to require treatment in the very young.
- Chiari I malformations may cause debilitating posttussive headaches that can be relieved with surgery. Chiari II malformations occur in patients with myelomeningocele and may be associated with brain stem compromise.
- Dandy-Walker syndrome is characterized by a posterior fossa cyst and cerebellar hypoplasia. It is associated with hydrocephalus and a number of systemic abnormalities.
- Meningoceles and encephaloceles are characterized by herniation of meninges or brain and meninges through a defect in the skull.
- Myelomeningocele is the most severe form of spinal dysraphism in which failure of primary neurulation leads to herniation of the spinal cord through defects in the vertebrae, soft tissue, and skin. Many children with myelomeningocele also suffer from hydrocephalus.

Hydrocephalus

Background

Hydrocephalus is a complex disease generally defined as a pathologic accumulation of cerebrospinal fluid (CSF) that leads to engorgement of the cerebral ventricles, mechanical deformation of brain structures, and increased intracranial pressure (ICP). Of relevance to the pediatric intensivist, these changes can render the patient critically ill. Thus a fundamental understanding of the condition is important for the clinician caring for these children in the intensive care setting.

Among children, hydrocephalus has an incidence of approximately 1 : 1000.[1-3] In

the United States, it accounts for approximately 40,000 hospital admissions and $2 billion in health care expenditures annually.[4] Children with hydrocephalus can be medically complex, and the number of hydrocephalus comorbidities has risen as our ability to care for affected children has improved.[4] These patients frequently require admission to an intensive care unit (ICU) for interventions related to their hydrocephalus and comorbid conditions.

Pathophysiology

CSF physiology and the pathophysiology of hydrocephalus are incompletely understood and remain an area of ongoing research. The prevailing hypothesis describes a *bulk flow* model, in which the CSF produced by the choroid plexus epithelium and the ependymal lining of the ventricles passes through the ventricular system, down the aqueduct of Sylvius, out the foramina of Luschka and Magendie, and into the spinal subarachnoid space. From there, the fluid continues through the subarachnoid spaces of the basal cisterns and the cerebral convexities until it reaches the arachnoid granulations, where it is reabsorbed into the venous system (Fig. 61.1). According to this theory, obstruction at any point in this pathway leads to an accumulation of CSF proximal to the blockage and, consequently, hydrocephalus. The term *noncommunicating* is used when there is an obstruction within the ventricular system; *communicating* hydrocephalus refers to obstruction at the level of the subarachnoid spaces, the arachnoid granulations, or the venous system.[1,5]

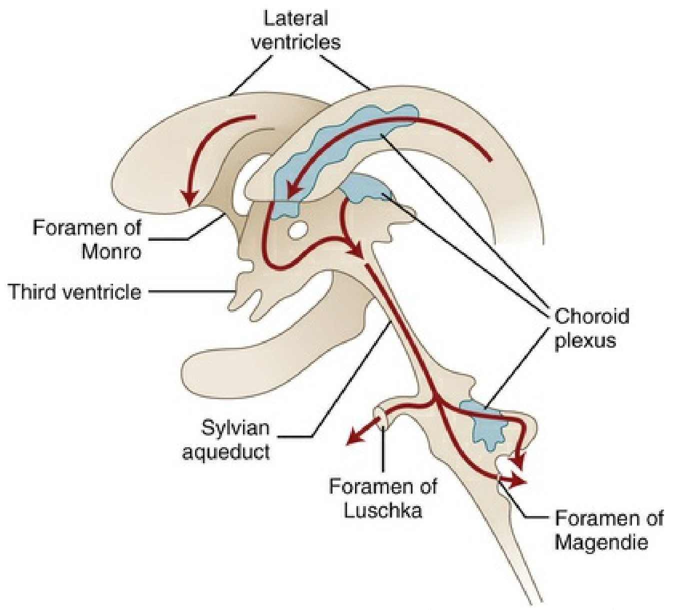

FIG. 61.1 The cerebral ventricular system. Cerebrospinal fluid flows from the lateral ventricles through the foramina of Monro, into the third ventricle, and down the cerebral ("Sylvian") aqueduct. It then passes through the fourth ventricle before finally exiting the ventricular system through the foramina of Magendie and Luschka. (Reproduced with permission from Hdeib A, Cohen AR. Hydrocephalus in children and adults. In: Ellenbogen RG, Abdulrauf SI, Sekhar LN, eds. Principles of Neurological Surgery. 3rd ed. Philadelphia: Saunders; 2012:105-127.)

With accumulation of CSF, ICP begins to rise. As with any rigid container,

pressure within the cranial vault is determined by its contents. In healthy patients, these include the brain, intravascular blood, and CSF. When mass lesions such as tumors or hematomas are present, they constitute an additional compartment and place stress on the system. Under normal circumstances, the body is able to accommodate pressure through the capacitance provided by veins, CSF, and, to a minor extent, the brain itself. The venous structures contain the majority of intracranial blood and have the lowest pressure and greatest compliance of the three; they are readily compressed as other compartments enlarge. Similarly, CSF drains from the ventricles into subarachnoid space and, ultimately, into the venous system in response to mass lesions. The brain itself can also become compressed and provides further accommodation, although this is typically the least compliant compartment. This system is able to minimize pressure changes in response to small challenges, but eventually the ability to compensate is exhausted and ICP elevates. Patients with untreated hydrocephalus are particularly vulnerable, as the CSF compartment offers little to no additional compliance.

Although enlargement of the ventricles because of the accumulation of CSF does cause mechanical deformation of the adjacent brain, the principal concern is control of ICP. Numerous studies have shown a strong association between persistently elevated ICP and poor outcome in the setting of trauma,[6] and intuitively the same association holds true in the case of hydrocephalus. Prompt identification and treatment of intracranial hypertension is therefore imperative.

Clinical Presentation

The clinical manifestations of untreated hydrocephalus depend on the age of the patient. In older children and adults, headache is the most frequent symptom. Nausea, vomiting, and somnolence are also common. Some patients develop an ataxic gait, and visual symptoms such as blurry vision, Parinaud syndrome, or diplopia due to cranial nerve VI palsies may also be seen. Younger children and nonverbal adults may become unusually irritable or intolerant of feeding. Infants with open cranial sutures will demonstrate fullness of the fontanelle and splaying of the suture lines.

Left untreated, these symptoms typically progress to frank lethargy, obtundation, and coma. Late in the course of the disease, bradycardia, hypertension, and abnormal respirations may be seen. This triad, frequently referred to as the Cushing reflex, is a sign of dangerously elevated ICP and frequently heralds impending herniation. These signs are not seen universally, however, so their absence should not necessarily be reassuring in comatose patients. Conversely, patients with bradycardia who are awake and talking are likely not on the verge of herniation, even if they have a history of hydrocephalus.

Causes

In North America, the most commonly identified causes of hydrocephalus are intraventricular hemorrhage (IVH) of prematurity (25%), brain tumors (18%), and myelomeningocele (15%); idiopathic cases account for approximately one-quarter of the total.[7] Postinfectious hydrocephalus is relatively rare in North America (under 4%) but accounts for as many as 60% of cases in sub-Saharan Africa.[7,8]

Diagnosis

Clinical history and physical examination are helpful, but imaging studies with enlarged ventricles are essential to establish the diagnosis. Newborns with IVH of prematurity, myelomeningocele, and other risk factors for hydrocephalus are frequently screened with cranial ultrasounds for ventricular enlargement. In borderline cases not requiring immediate intervention, serial imaging studies and head circumference measurements can be helpful in confirming the need for treatment. The presence of papilledema, a bulging fontanelle, or widely splayed sutures can help to corroborate imaging findings or symptoms concerning for intracranial hypertension and guide treatment decisions.

Management

The principal treatment for hydrocephalus is diversion of cerebrospinal fluid. This goal can be achieved temporarily with an external ventricular drain (EVD) tunneled out through the scalp or permanently with an internalized CSF shunt. In selected patients, endoscopic third ventriculostomy (ETV) with or without choroid plexus cauterization may also be an alternative.

Children with acute hydrocephalus can be critically ill and may require emergent EVD placement, a rapid procedure that is performed at the ICU bedside in some institutions. If the child is deteriorating and an EVD cannot be placed immediately, standard methods for controlling ICP should be employed: elevation of the head of the bed and neutral neck positioning to facilitate venous drainage, administration of analgesics and sedatives, mild hyperventilation with a target $PaCO_2$ of 30 to 35 mm Hg, and hyperosmolar therapy with mannitol or hypertonic saline.[6] Hypotension should be avoided to maintain cerebral perfusion. Because patients with acute hydrocephalus frequently have altered mental status, intubation may be required for airway protection.

An EVD may also be used nonemergently in the setting of a neurosurgical operation to facilitate drainage of debris and blood products from the ventricular system. In this case, the goal is prevention of hydrocephalus.

To place an EVD, a craniostomy is created through a small skin incision behind the hairline, and a catheter is then passed through the brain parenchyma into the lateral ventricle. The other end of the catheter is then tunneled out through the scalp and connected to a bedside collection system, which can be raised and lowered to control the amount of CSF drained. The typical reference point is the patient's external acoustic meatus (EAM). These drains require close monitoring and frequent adjustments to maintain the proper height with changes in patient position; if they are not leveled appropriately, over- or underdrainage of CSF may result, with potentially serious consequences. At some centers, the level of monitoring required is available only in the ICU, and it is not uncommon for patients who are otherwise well to be kept in the ICU for days at a time until their EVDs are removed. When it is thought that the drain is no longer needed, many neurosurgeons “wean” the drain by raising it progressively and ultimately clamping it. If this process is well tolerated without symptoms or imaging evidence of hydrocephalus, the drain is removed; if it is not, a shunt is usually required.

CSF shunting systems are the standard treatment for patients requiring permanent

CSF diversion. A variety of shunt constructs are used, but the general form is a ventricular catheter connected in series to a valve and a distal catheter (Fig. 61.2). The distal catheter is tunneled subcutaneously to the peritoneum most commonly, but in some children it is placed in the right cardiac atrium or pleural space. The shunted CSF is then reabsorbed within the distal compartment. Although shunt placement is lifesaving the devices are subject to failure. Patients with occluded shunts usually present with the typical symptoms of hydrocephalus as CSF accumulates, and imaging studies usually demonstrate enlargement of the ventricles (Fig. 61.3). A subset of patients—usually those with complex neurosurgical histories—may have atypical presentations or ventricles that do not enlarge.

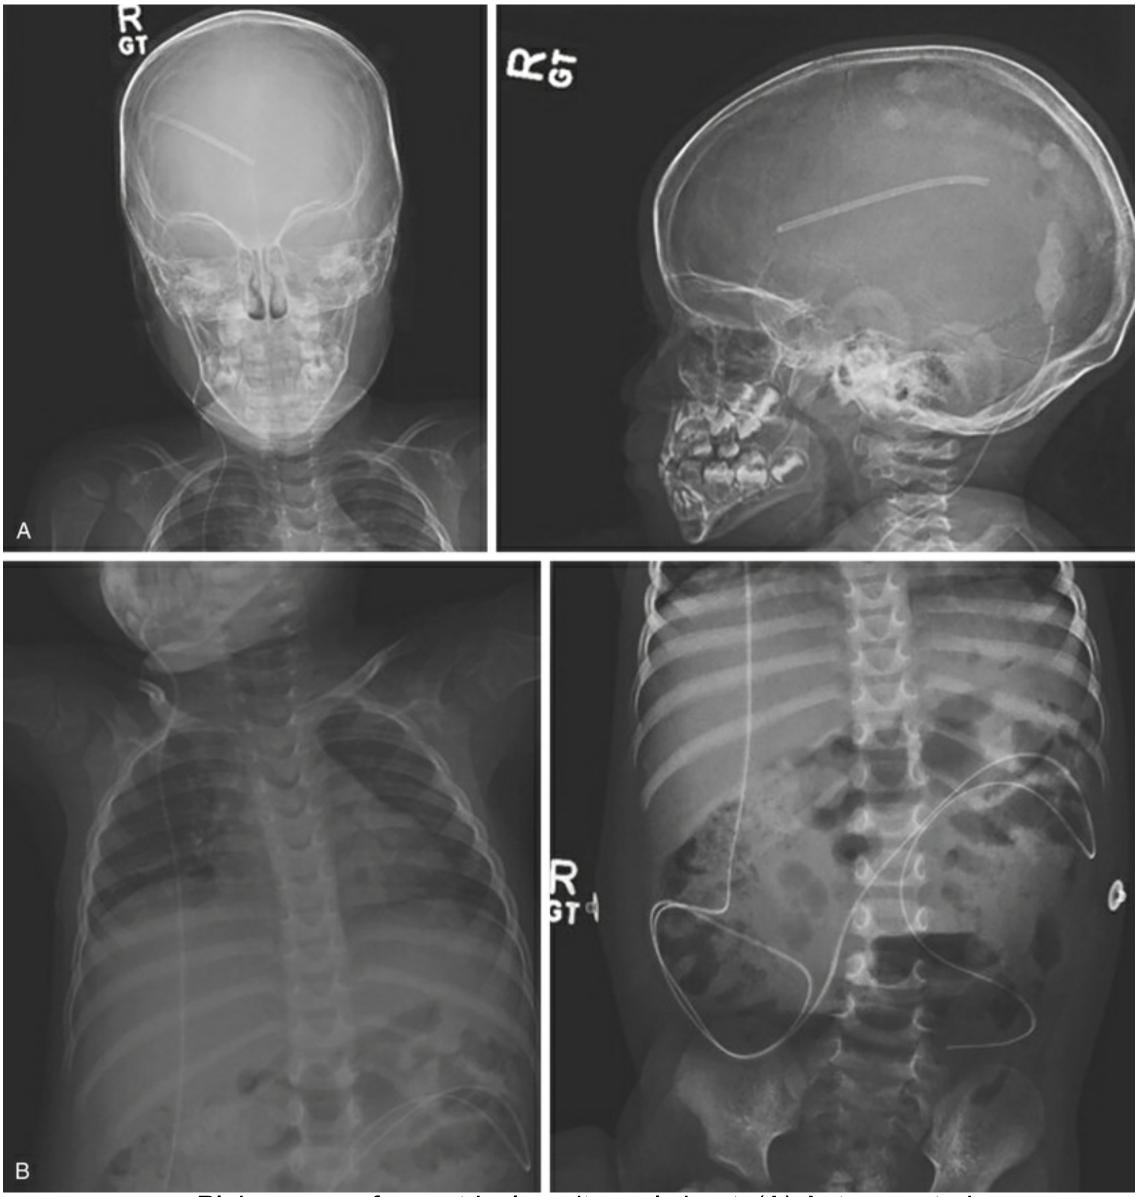

FIG. 61.2 Plain x-rays of a ventriculoperitoneal shunt. (A) Anteroposterior and lateral cranial x-rays show the ventricular catheter connected to a valve with radiolucent tubing. The proximal portion of the peritoneal catheter is seen attached to the distal end of the valve. (B) Anteroposterior chest and abdominal films show the course of the peritoneal catheter down the neck, over the clavicle and ribs, and into the

peritoneal cavity. (Reproduced with permission from Hdeib A and Cohen AR. Hydrocephalus in children and adults. In: Ellenbogen RG, Abdulrauf SI, Sekhar LN, eds. Principles of Neurological Surgery. 3rd ed. Philadelphia: Saunders; 2012:105-127.)

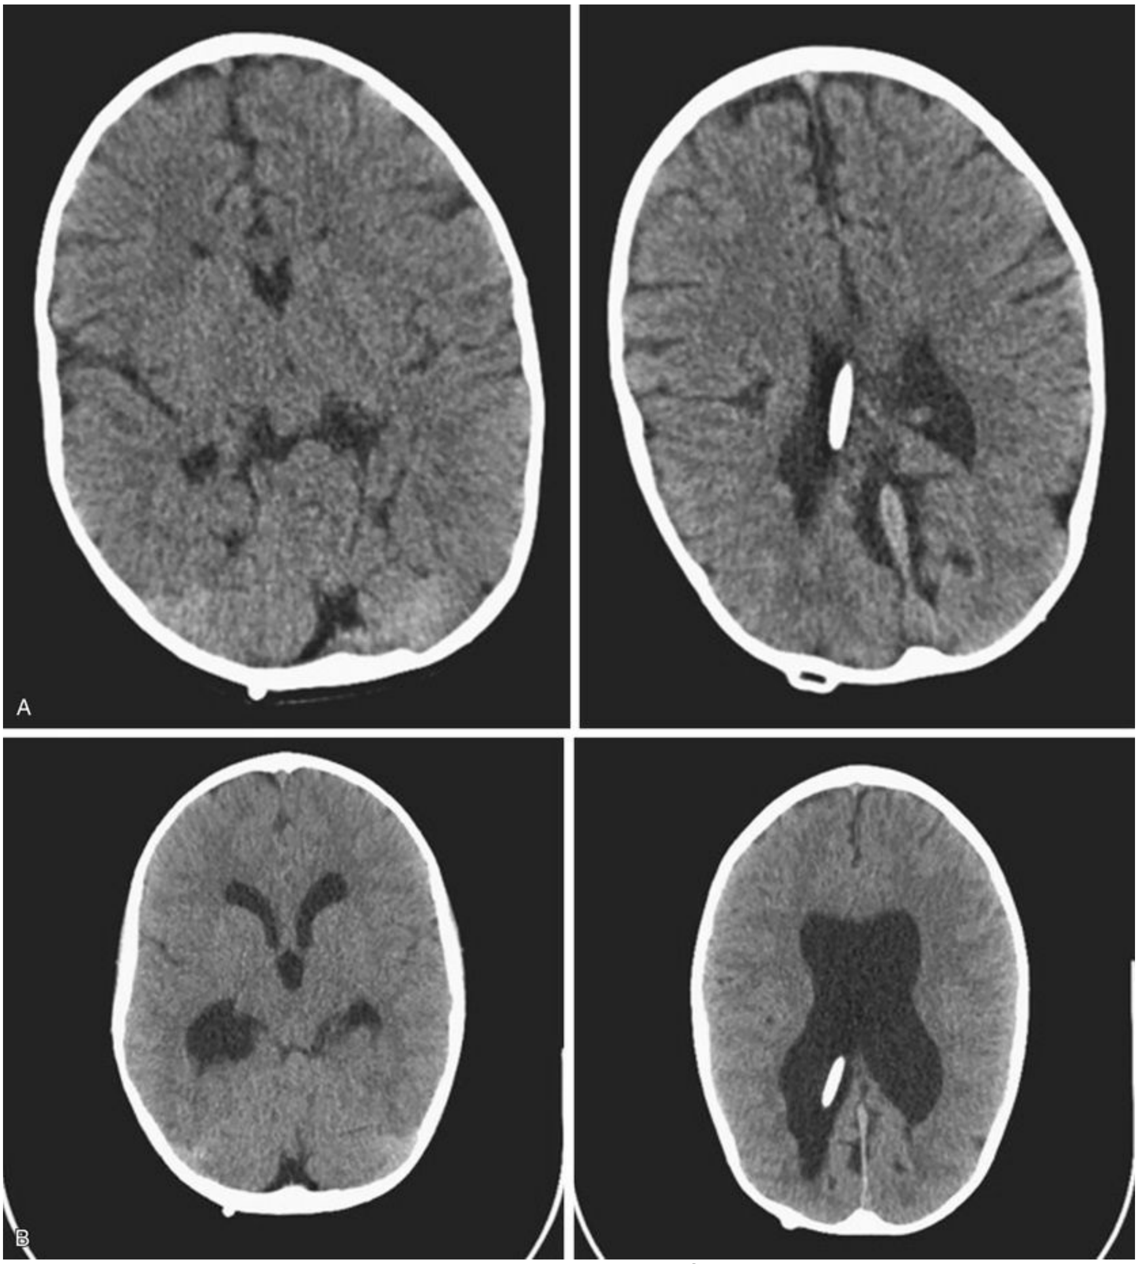

FIG. 61.3 Ventriculoperitoneal shunt malfunction causing ventriculomegaly. (A) Axial computed tomography shows small ventricles with a properly functioning ventriculoperitoneal shunt. (B) With shunt failure, the ventricles are enlarged. (Reproduced with permission from Hdeib A, Cohen AR. Hydrocephalus in children and adults. In: Ellenbogen RG, Abdulrauf SI, Sekhar LN, eds. Principles of Neurological Surgery. 3rd ed. Philadelphia: Saunders; 2012:105-127.)

A failed shunt is a medical emergency requiring immediate neurosurgical intervention for shunt revision. Infection of the shunt hardware can also occur, most commonly due to seeding at the time of surgery. Patients generally present with

fever and meningeal symptoms; shunt failure may also be present, and drainage of infectious material into the abdomen may lead to the formation of a pseudocyst or frank peritonitis. If untreated, the infection may progress to ventriculitis, which carries a poor prognosis. Treatment requires surgical removal of the shunt hardware and placement of a temporary EVD until the infection is cleared. After a prolonged course of antibiotics (upward of 2 weeks for some organisms), the shunt may be replaced if CSF cultures remain negative. On average, children with a history of shunt infection have a significantly lower IQ than controls without infection.[9] Fortunately, application of a standardized protocol has been shown to substantially reduce the rate of shunt infection to approximately 5%.[10]

In a selected subset of patients, ETV can provide permanent treatment of hydrocephalus without the need for a shunt.[11,12] In this procedure, a fenestration is made at the floor of the third ventricle, providing an alternative route for CSF drainage.

Arachnoid Cysts

Background

Arachnoid cysts are congenital anomalies filled with fluid similar or identical to CSF and lined by thin membranes of arachnoid (Fig. 61.4). They have an incidence of 0.5% to 2.5%[13] and are more common in males. Although arachnoid cysts can occur anywhere along the neuraxis, they are most commonly found in association with an arachnoid cistern, and approximately half are located in the Sylvian fissure.[14,15]

FIG. 61.4 Arachnoid cyst. T2-weighted magnetic resonance image shows a large right middle fossa arachnoid cyst. Note that the signal intensity of the cyst contents is identical to that of cerebrospinal fluid. (Reproduced with permission from Jimenez DF, Gentry Savage J, Samuelson M. Developmental anomalies. In: Ellenbogen RG, Abdulrauf SI, Sekhar LN, eds. Principles of Neurological Surgery. 3rd ed. Philadelphia: Saunders; 2012:129-135.)

It was previously thought that arachnoid cysts were related to agenesis of the adjacent brain region; however, modern radiographic techniques have clarified that there is no difference in brain volume between the side with an arachnoid cyst and the side without. Instead, the brain is displaced and, in some cases, the overlying skull is expanded.[16,17]

Clinical Presentation

Generally asymptomatic, most of arachnoid cysts are found incidentally and do not change in size; however, a small subset can progressively enlarge and cause mass effect on adjacent structures. In these cases, the effects are generally referable to the location of the lesion, and symptoms of intracranial hypertension may be seen. If the CSF pathway is involved, hydrocephalus can result. In the special case of suprasellar arachnoid cysts, endocrinopathy, visual impairment, and hydrocephalus may result.[18] Fortunately, growth of arachnoid cysts is typically seen only in the very young; in one series of more than 300 cases, no patient over the age of 4 experienced cyst enlargement or required surgical intervention.[16,19]

Rarely, children may present with hemorrhage, either into the cyst itself or into the overlying subdural space. As with any intracranial hemorrhage, these cases represent a medical emergency and require prompt neurosurgical attention. Operative interventions may be required to evacuate the hematoma.

Diagnosis

When a suspected arachnoid cyst is identified, definitive imaging with contrast-enhanced magnetic resonance imaging (MRI) should be performed to rule out other pathology. If the diagnosis of arachnoid cyst is confirmed, close clinical and radiographic follow-up is warranted for young children because of the increased risk of enlargement among this age group.[13] As the patient ages, the need for serial imaging studies decreases. When arachnoid cysts are identified in teenagers and young adults, a single stable follow-up image is often sufficient.

Management

Surgical intervention for arachnoid cysts is reserved for cases with progressive growth or concerning mass effect; asymptomatic, small lesions that do not enlarge are generally left untreated, regardless of their location and size. When an operation is indicated, placement of a cyst-to-peritoneal shunt is usually the procedure of choice, although open or endoscopic operations to fenestrate the cyst wall may also be performed.

Chiari Malformations

Four types of Chiari malformations have been described. Although they share a common name and some morphologic features, they are actually distinct pathologies; they do not represent separate points along the spectrum of a single disease.

Chiari I Malformation

A Chiari I malformation is defined by the presence of cerebellar tonsillar ectopia with the inferior tip of the tonsils at least 5 mm below the level of the foramen magnum (Fig. 61.5). The low-lying tonsils can interfere with the normal flow of CSF across the foramen magnum and cause suboccipital headaches that are brought on by coughing or a Valsalva maneuver. These maneuvers result in transient venous hypertension, which is propagated to the brain parenchyma. In patients without Chiari malformations, CSF egress through the obex of the fourth ventricle accommodates the pressure increase by allowing CSF to exit the ventricles. The Chiari malformation is thought to impede flow through this pop-off valve, resulting in a temporary spike in pressure and, consequently, headaches. Headaches that are not posterior and not elicited by provocative maneuvers are unlikely to be due to the Chiari malformation.[20]

FIG. 61.5 Chiari I malformation. Sagittal T1-weighted magnetic resonance image shows ectopia of the cerebellar tonsils far below the foramen magnum, consistent with a Chiari I malformation. Note the peglike morphology of the tonsils, which are present more commonly in symptomatic lesions. (Reproduced with permission from Tubbs RS, Hankinson TC, Wellons JC. The Chiari malformations and syringohydromyelia. In: Ellenbogen RG, Abdulrauf SI, Sekhar LN, eds. Principles of Neurological Surgery. 3rd ed. Philadelphia: Saunders; 2012:157-168.)

Some patients with Chiari I malformations may also develop syringomyelia.[21] The mechanism by which the syrinx develops is not completely understood, but some have hypothesized that the blockage at the obex redirects CSF flow down the central canal of the spinal cord, resulting in cavitation and cyst formation.[22,23] As a consequence, these patients can have symptoms of myelopathy, including extremity weakness, sensory changes, gait imbalance, and bowel/bladder incontinence. In particularly severe cases, compression of the brain stem by the Chiari I malformation can cause lower cranial nerve dysfunction. These patients may experience dysphagia, dysarthria, or tinnitus.[24] Hydrocephalus is present only rarely.[21]

Chiari I malformation is best diagnosed with an MRI of the brain, which will show

in detail the anatomy of the cerebellar tonsils and the brain stem. Patients with round-appearing tonsils close to 5 mm below the foramen magnum are less likely to be symptomatic, whereas those who have more profound tonsillar descent with peg-shaped morphology are more likely to be symptomatic and to benefit from surgery. Cine MRI can also demonstrate obstruction to the normal pulsatile flow of CSF at the foramen magnum.[25,26] Our practice is to routinely obtain an MRI of the spine on all patients with a Chiari I malformation to rule out syringomyelia.

The decision to surgically treat a Chiari I malformation is influenced principally by symptomatology. Patients with lifestyle-limiting headaches and convincing radiographic findings are usually offered an operation, whereas those who are asymptomatic can be observed safely and treated if they develop symptoms.[24,27] Patients with syringomyelia are an exception to this rule; we generally recommend surgical decompression for these patients even in the absence of symptoms to prevent syrinx progression and spinal cord damage.

The goal of surgery is decompression of the cerebellar tonsils and brain stem. To accomplish this objective, a midline suboccipital incision is made, and the posterior arch of C1 and the posterior rim of the foramen magnum are identified and removed. In most patients, the dura is then opened and a dural patch is sewn in place to expand the dural sleeve.[28] If the tonsils are particularly low lying, bipolar cautery can be used to shrink the tonsils. This latter maneuver does not result in lasting neurologic deficits, although patients may experience a subtle, temporary ataxia. Although the postoperative course is generally uneventful, patients are commonly admitted to the ICU overnight to be monitored for neurologic decline or respiratory depression, the latter of which can occur in up to 14% of cases.[24]

Chiari II Malformation

By definition associated with myelomeningocele, the Chiari II malformation is characterized by low-lying cerebellar tonsils with caudal displacement of the brain stem and fourth ventricle. Hydrocephalus is present in most cases because of the associated myelomeningocele. Many developmental abnormalities may be associated with a Chiari II malformation, including a small posterior fossa, polymicrogyria, gray matter heterotopias, and hypoplastic brain stem nuclei.[20]

When symptomatic, neonates and young infants tend to present with signs and symptoms referable to brain stem and lower cranial nerve dysfunction. Neonates may have apneic episodes, which can be due to untreated hydrocephalus or to maldevelopment of the medullary respiratory center. Inspiratory stridor and neurogenic dysphagia may also result from brain stem abnormalities.[29-31] In general, younger patients with more rapid presentations tend to have worse outcomes. In older children, syringomyelia can cause myelopathy and extremity weakness.

Surgical management of Chiari II malformation is similar to that of Chiari I malformation; however, the posterior fossa venous anatomy tends to be atypical in these patients, and our experience is that the expansion duraplasty carries much higher risk in this group. As such, we do not routinely open the dura in these patients.

Chiari III Malformation

Chiari III malformations account for fewer than 1% of all Chiari malformations.[20] They are characterized by occipital or cervical encephaloceles containing tissue from the cerebellum and, in some cases, the brain stem. Hydrocephalus is very common, and severe developmental problems are nearly universal. Surgical treatment for these patients involves repair of the encephalocele.[20]

Chiari IV Malformation

Unlike types I, II, and III, the Chiari IV malformation is not characterized by herniation of brain tissue but is instead an extreme form of cerebellar hypoplasia. Maldevelopment of the brain stem is occasionally seen in this condition. Surgical decompression is not required.

Dandy-Walker Malformation

The Dandy-Walker malformation is defined by an enlarged posterior fossa, cystic dilatation of the fourth ventricle, and vermian hypoplasia or aplasia (Fig. 61.6). It occurs with a frequency of approximately 4 per 100,000, and between 70% and 90% of patients have hydrocephalus, which is the presenting feature in most.[15,32,33] About two-thirds of patients have associated central nervous system (CNS) malformations, with agenesis of the corpus callosum being most common. Meningoceles, encephaloceles, agyria, polymicrogyria, intrinsic brain stem malformations, and others are also seen.[32,34] Some[35-37] but not all [38,39] authors have found a correlation between the presence of these structural abnormalities and intelligence, which is normal in approximately 40% of patients.[36] Epilepsy and sensory disturbances are not infrequent, and these have been consistently shown to correlate with worse cognitive outcome.[35]

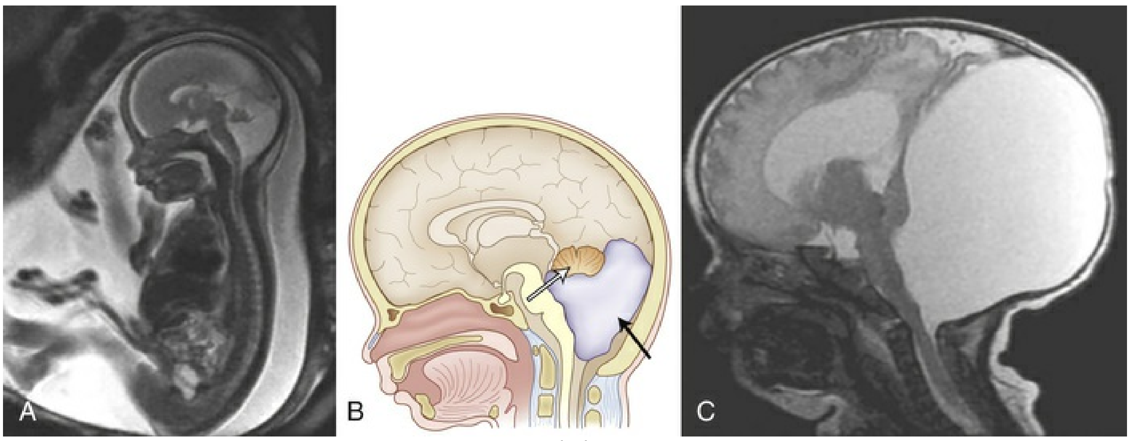

FIG. 61.6 Dandy-Walker syndrome. (A) Prenatal sagittal T2-weighted magnetic resonance image shows a large posterior fossa cyst and abnormal cerebellum, consistent with Dandy-Walker syndrome. (B) The black arrow indicates a large posterior fossa cyst, and the white arrow indicates an abnormal cerebellar vermis. (C) Sagittal T2-weighted magnetic resonance image shows a large posterior fossa cyst with upward displacement of the tentorium. (Reproduced with permission from Choutka O, Mangano FT. Dandy-Walker syndrome. In: Winn HR, ed. Youmans Neurological Surgery. Philadelphia:

Elsevier Saunders; 2011:1906-1910.)

Outside of the CNS, Dandy-Walker malformations are associated with a number of systemic anomalies that can be particularly relevant to the pediatric intensivist. For example, tetralogy of Fallot, congenital valve disease, coarctation of the aorta, ventriculoseptal defects, and a patent ductus arteriosus can compromise cardiovascular function in these children. Feeding and the digestive process can be complicated by duodenal atresia, intestinal malrotation, and anorectal malformations. Dysplasia of the kidneys and lungs may also occur. Finally, Dandy-Walker malformation is seen in many children with syndromic disorders.[34]

Management of the condition is neurosurgical. If present, hydrocephalus should be treated by placement of a CSF shunt or ETV.[33,40-45] Fenestration of the fourth ventricular cyst has fallen out of favor as a primary treatment because it is associated with unacceptable morbidity and mortality. It is generally not performed for patients whose hydrocephalus is adequately treated by a shunt; however, several authors have had satisfactory results in patients with recurrent shunt malfunctions.[46-48]

Encephalocele and Meningocele

Encephalocele and meningocele are two related malformations that are characterized by herniation of CNS contents through a skull defect. In an encephalocele, the herniated tissue comprises brain, CSF, and meninges (Fig. 61.7); in a meningocele, only CSF and meningeal tissue are involved.

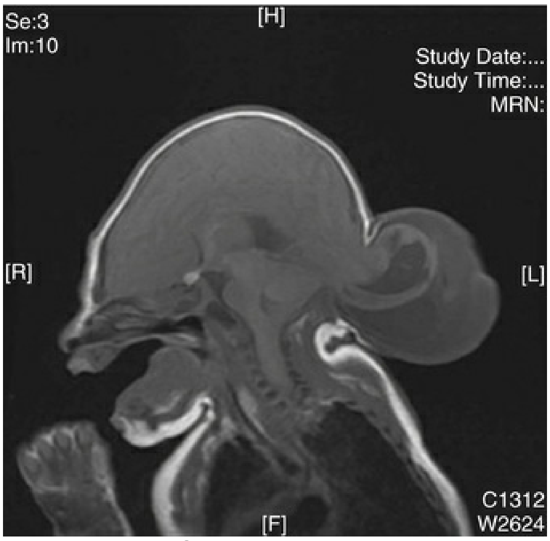

FIG. 61.7 Encephalocele. Sagittal T1-weighted magnetic resonance image shows an occipital encephalocele, with herniation of brain contents through a skull defect and into the sac. (Reproduced with permission from Ghatan S. Encephalocele. In: Winn HR, ed. Youmans Neurological Surgery. Philadelphia: Elsevier Saunders; 2011:1898-1905.)

Encephaloceles occur in approximately 1 to 3 per 10,000 live births and account for 10% to 15% of all neural tube defects.[49-51] Primary encephaloceles are developmental in origin, whereas secondary encephaloceles are acquired, most commonly because

of trauma, infection, malignancy, or surgery.[52]

Primary lesions are generally classified based on their location: at the skull base, in the anterior cranial fossa, or along the calvaria. The relative frequency of these lesions varies with the population studied; occipital encephaloceles (along the calvaria at the occiput) account for 80% of all cases in North America and Western Europe, whereas anterior encephaloceles are more common in Southeast Asia and Africa.[52-57] They may occur in isolation or in conjunction with other anomalies as part of a syndrome, such as in Meckel syndrome or amniotic band syndrome.[58-60]

Most of these lesions are now diagnosed prenatally with routine ultrasound examinations, prompting delivery of the fetus by cesarean section. If not seen on prenatal ultrasound, they are frequently obvious at birth.[52] Because clinically significant associated abnormalities are commonly seen throughout the neuraxis, patients with suspected or confirmed encephaloceles should be imaged with an MRI of the brain and spine.[52] As many as one-fifth will have an additional neural tube defect, and hydrocephalus is present in 16% to 65% of cases.[55,61-64] Neurologic function varies with the location of the lesion and the amount of brain matter in the encephalocele; children with small lesions may have no obvious neurologic findings, whereas more significant cases can present with severe deficits, including brain stem dysfunction not compatible with life.[52,65] Among patients with occipital encephaloceles, approximately 17% will have normal neurologic outcomes.[65]

Spinal Dysraphism

Spinal dysraphism refers to a spectrum of related malformations that range in severity from clinically insignificant to life altering. The mildest form, spina bifida occulta, is defined by a congenital absence of all or part of the posterior elements of a lumbar vertebral body. Many of these are found incidentally and cause the patient no harm, although some are associated with other abnormalities that predispose the patient to tethered cord syndrome. Spina bifida aperta is more severe and is divided into two subtypes: meningocele and myelomeningocele. The former is characterized by a more severe defect in the posterior elements than is seen with spina bifida occulta; there is cystic dilatation of the meninges, but the underlying neural structures are normal.[66]

Myelomeningocele is the most severe form, with exposure of the spinal cord and loss of function distal to the affected level (Fig. 61.8). The malformation is caused by failure of the posterior neuropore to close properly, which in turn prevents proper migration of the adjacent ectodermal tissues. As a consequence, the involved segment of the spinal cord is exposed as a *placode* surrounded by fragile arachnoid membranes that tether to the neural tissue to the adjacent skin. These membranes frequently rupture, leading to loss of CSF and increased risk of infection. Chiari II malformations are present in most of these children.[67]

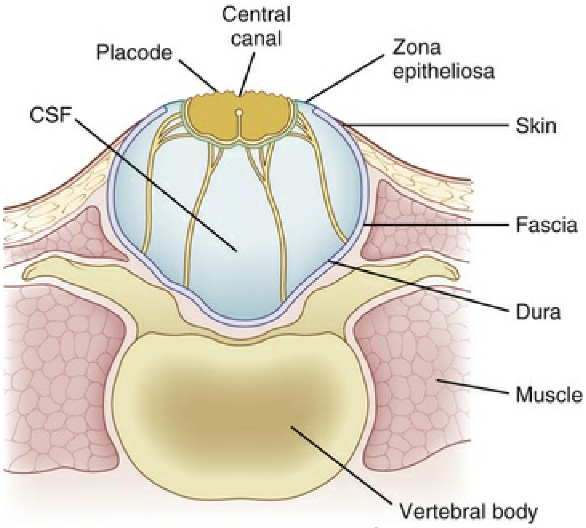

FIG. 61.8 Axial cross-sectional anatomy of a myelomeningocele. Due to failure of primary neurulation, the spinal cord herniates through defects in the vertebrae and soft tissue and is exposed as the placode. The placode is surrounded by the zona epitheliosa, a thin layer of epithelial tissue. (Reproduced with permission from Sutton LN, Bauman JA, Macyszyn LJ. Spinal dysraphism and tethered spinal cord. In: Ellenbogen RG, Abdulrauf SI, Sekhar LN, eds. Principles of Neurological Surgery. 3rd ed. Philadelphia: Saunders; 2012:89-103.)

Timely closure of the myelomeningocele is imperative to reduce the risk of infection, which increases after 24 to 36 hours of life because of bacterial colonization.[68] To prevent further loss of function, the newborn should be positioned prone to keep pressure off of the lesion. In addition, the site should be kept moist with saline and covered with saline-soaked Telfa pads.[67] At our center, we commonly place a "donut" of soaked, sterile sponges around the placode, which ensures that the overlying dressing does not apply pressure to the lesion.

Precise surgical techniques for repair vary from center to center. At our institution, the procedure is carried out by a combined team of neurosurgeons and plastic surgeons. The neurosurgeon releases the placode and closes the dura in a watertight fashion to prevent leakage of CSF; the plastic surgery team then mobilizes adjacent soft tissue flaps to perform a layered closure (Fig. 61.9).[69] As in the preoperative period, the patient is kept prone postoperatively to prevent pressure on the wound. Use of narcotics should be limited; many patients are unusually susceptible to the respiratory suppression that these agents cause because of either intrinsically hypoplastic brain stem nuclei or extrinsic compression from associated Chiari II malformations.

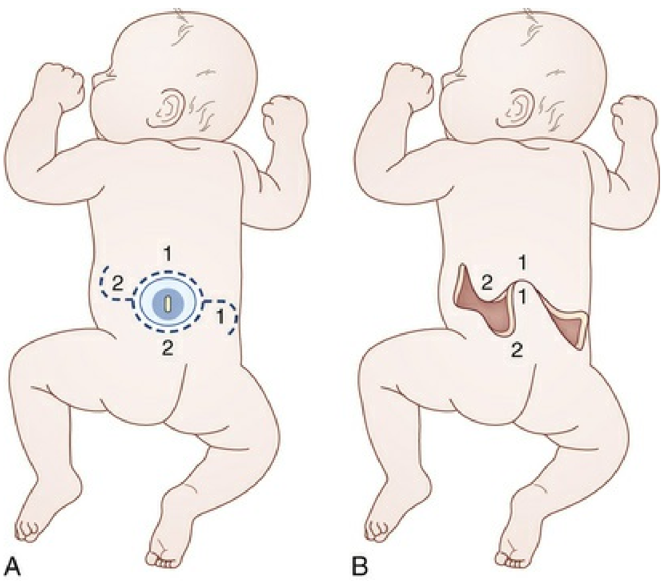

FIG. 61.9 Closure of the myelomeningocele. (A) Once the placode is released and the dura is closed, creation of tissue flaps may be required to close larger defects. Here, an S-shaped incision surrounds the lesion. (B) The tissue flaps are rotated, facilitating a multilayered closure. (Reproduced with permission from Sutton LN, Bauman JA, Macyszyn LJ. Spinal dysraphism and tethered spinal cord. In: Ellenbogen RG, Abdulrauf SI, Sekhar LN, eds. Principles of Neurological Surgery. 3rd ed. Philadelphia: Saunders; 2012:89-103.)

As many as 85% of children with myelomeningocele have comorbid hydrocephalus, with more proximal lesions conferring a higher risk of shunt dependence.[67,70] Thus these children should undergo intracranial imaging to evaluate for ventriculomegaly. Practice patterns vary among surgeons and centers, but in general children with overt hydrocephalus on imaging undergo placement of either a temporary EVD or a permanent shunt at or around the time of their myelomeningocele closure. If the neurosurgeon elects not to place an EVD or a shunt, the child must be watched closely for signs and symptoms of untreated hydrocephalus, including a tense fontanelle, splayed sutures, rapidly increasing head circumference, ventricular enlargement on serial ultrasounds, or leakage of CSF from the site of myelomeningocele closure. The presence of any of these conditions usually signals the need for shunt placement.

Ultimately, outcome depends on the level of the lesion and the presence of hydrocephalus. Proximal lesions at T12 or L1 cause complete or nearly complete paralysis of the lower limbs, whereas distal lesions at S1 or S2 may cause only mild distal motor symptoms and sphincter dysfunction. About half of patients have the ability to ambulate with a brace. Seventy percent of patients achieve normal IQ, although that rate is far lower among children who suffer a shunt infection.[68]

CHAPTER 62

Neurologic Assessment and Monitoring

Mark S. Wainwright

PEARLS

- Much of the practice of brain-directed critical care in children is empirical, but studies in traumatic brain injury support the use of protocol-directed care with multidisciplinary teams in the intensive care unit to reduce mortality.
- The examiner should focus on both localizing a neurologic deficit and identifying mechanisms of injury (or potential injury) as the first steps in developing a treatment approach to reduce brain injury.
- Communication between team members, serial examinations, anticipation, and early recognition of changes in the neurologic exam or other monitoring parameters are essential.
- Metabolic monitoring methods, including partial pressure of oxygen and microdialysis, have great potential to advance the detection of, and therapy for, secondary neurologic injury in pediatric acute brain injury. The application of these tools to neurocritical care and the demonstration of their efficacy in improving outcomes will require advances in data collection, bioinformatics, and methods of data analysis.

Overview and Basic Principles of Pediatric Critical Care Neurology

The approach to the neurologic assessment of the patient in the pediatric or cardiac intensive care unit (ICU) requires an interdisciplinary team involving intensivists, neurologists, neurosurgeons, and specialists from allied disciplines including physiatry and psychiatry. Examples of these programs at different pediatric academic centers have been published.[1-4] Although this method recapitulates elements of the approach to differential diagnosis used in the outpatient setting and inpatient care outside the ICU, there are fundamental differences that are specific to the practice of pediatric critical care neurology.[5,6] In general, these differences

involve the need to obtain testing (imaging, neurophysiology, laboratory) on patients who may appear neurologically intact, the need to intervene before a specific neurologic diagnosis has been obtained or mechanism of injury confirmed, and the challenge of determining whether such interventions affect long-term outcome. Indeed, the lack of data from randomized controlled clinical trials to guide much of the management of children with acute brain injuries is a defining feature of the practice of neurologic critical care in children.

In sum, the practice of pediatric critical care neurology involves the need for serial neurologic examinations, clear communication between nurses and physicians and among practitioners of multiple medical services, the need for an early recognition of changes in the neurologic exam, and the anticipatory management of patients with the potential for progressive neurologic deterioration. The confounding effects of sedation or postoperative anesthesia on neurologic functioning pose an additional set of challenges to the assessment of these patients. Nevertheless, a logical approach to the neurologic examination is possible, using the standard structure of a neurologic examination, combining this exam with attention to the mechanisms of injury (present or potential) and thereby developing a plan for ongoing monitoring and management. Last, it is prudent to regard every patient in the pediatric ICU (PICU) as having the potential for neurologic complications of his or her illness. These patients with primary diagnoses ranging from neurologic complications of solid organ transplant to liver failure to congenital heart disease may suffer neurologic injury from any combination of hypoxic, ischemic, inflammatory, or metabolic cerebral insults.

Recognition of Neurologic Complications of Critical Illness

This is likely an underrecognized population in many PICUs, in part because of the prevalence of nonconvulsive seizures (NCSs)[7,8] or ICU-acquired weakness.[9] In these cases, the recognition of new neurologic deficits relies on the ability of the medical team to recognize changes in the neurologic exam. In general, interventions to treat or attenuate neurologic insults, whether seizures, ischemia, or increasing intracranial pressure (ICP), are more likely to be successful if initiated early in the process of injury. This means that effective neurologic monitoring in the PICU does not rely solely on the availability of a neurologist, electroencephalogram (EEG), or neuroimaging. Rather, the prerequisite to using these monitoring tools is a high index of suspicion for new neurologic injury on the part of the medical team for patients who do not have primary neurologic injuries.

In addition to the physical exam, a number of modalities are used for to monitor neurologic function in critically ill children and adults (some suggestions for review can be found in the references[10,11]). These include continuous EEG monitoring (which is well established as a modality essential for the detection of NCS in the adult and PICU[12-15] ICP), transcranial Doppler (TCD),[16,17] and metabolic tissue oxygen monitoring.[18-20] Thresholds for detecting cerebral ischemic injury have been proposed for brain oxygen tension[21] and near-infrared spectroscopy (NIRS).[22] With respect to pediatric neuromonitoring, as yet there is no consensus on normal values or the age-dependence of these end points.[23]

Anticipatory Planning for New Neurologic Deficits

The ability to recognize changes in the neurologic exam is an essential component of brain-directed critical care for children. Reliance on technology alone is insufficient. Management should include the anticipation of specific changes in the patient's exam, an understanding of the pathophysiology causing that change, and a predetermined plan to intervene and address that mechanism. Common examples include compromise of short-term memory in the patient with acute liver failure (ALF), right leg weakness in the patient with right anterior cerebral artery stroke, and hypophonia in the patient with acute inflammatory demyelinating polyneuropathy. Each example (progression of hepatic encephalopathy, compression of the left anterior cerebral artery caused by increased edema in the right frontal lobe, progression to involve bulbar weakness) requires an escalation in care and cannot be identified by bedside monitors other than an examiner with an understanding of the disease process and the implications of these findings.

An improving exam despite deterioration in other modalities such as EEG, TCDs, ICP, or neuroimaging may change the treatment plan. Similarly, deterioration in the neurologic exam may occur without changes in these other measures. The ability to detect and react to such change requires a consensus on the admission neurologic exam, consensus on the criteria for decline or improvement for each specific patient, and anticipatory planning for the management of changes in the exam. The examiner should first discuss the neurologic findings with the bedside nurse and other members of the medical team. If possible, abnormal findings should be demonstrated to the members of the team. There should be a consensus on the key findings and the approach to be taken for evaluation and management if the neurologic exam changes. The improvements in outcome for children with severe traumatic brain injury (TBI) associated with the introduction of a multidisciplinary care team[24] and adherence to management guidelines[25] suggest that an emphasis on consistent care following established protocols can improve outcome without the need for additional technology (see also Chapter 119).

History and Assessment of Risk Factors

For children in the PICU, the medical history may provide essential information about the mechanisms and timing of neurologic insult. This information is needed for the interpretation of the neurologic exam and assessment of potential mechanisms of neurologic injury. These data are then used to assess the risk for progression of neurologic injury, to prioritize therapeutic interventions, and to determine the need for and timing of additional evaluations including imaging, EEG, and laboratory studies. In many cases, decisions to treat (or not treat) a neurologic injury in the PICU have to be empiric and based on a careful assessment of risk factors, potential mechanisms of injury, and weighing of the risks and benefits of such intervention. For example, the approach to the evaluation of altered mental status presenting to the PICU will be different with children with an established complex partial seizure disorder, those with sickle cell disease, or stem cell transplant recipients on immune suppressant drugs. Before examining the patient, knowledge of salient details of the medical history allows the examiner to begin to formulate a diagnostic approach and to prepare the early steps in management. The patient with a history of epilepsy in the preceding example would likely require an

emergent EEG to rule out nonconvulsive seizures, whereas the patient with sickle cell disease and risk factors of vascular injury with the same symptoms may require an imaging study and the immune suppressed patient a lumbar puncture. The presenting neurologic symptoms may be similar, but the history dictates the assessment based on the likely mechanisms producing the deficits found on neurologic examination.

Iatrogenic Complications of Pharmacotherapy

A review of medications should be part of the neurologic assessment of any patient with new neurologic symptoms. The initial assessment of the patient should include attention to medications that cross the blood-brain barrier or that may interfere with the renal or hepatic metabolism of centrally active drugs. In patients in renal or liver failure or in those requiring dialysis, the side effects of a centrally acting drug must be considered in the differential diagnosis for any neurologic symptom. This may occur even in the presence of "normal" doses of drugs or levels of anticonvulsants, as off-target drug toxicities may be due to metabolites, not the drug itself. An example is shown (Fig. 62.1) of a child with a mild static encephalopathy and spasticity, on dialysis as the sequelae of perinatal renal injury, who developed progressive encephalopathy. Treatment with flumazenil and an immediate improvement in mental status confirmed that the accumulation of baclofen in this dialysis-dependent patient was the source of a waxing and waning encephalopathy. Common examples in the PICU include immunophilin-associated seizures, encephalopathy and hypertension, oculogyric crisis, delirium during reduction of sedation, and prolonged sedation and paralysis from overzealous neuromuscular blockade. In many cases, the attribution of the symptoms to a drug side effect (excess level, too rapid withdrawal, idiosyncratic reaction, impairment of clearance) will be a diagnosis of exclusion. Nevertheless, a review of medications and recent changes should be a routine component of the neurologic assessment.

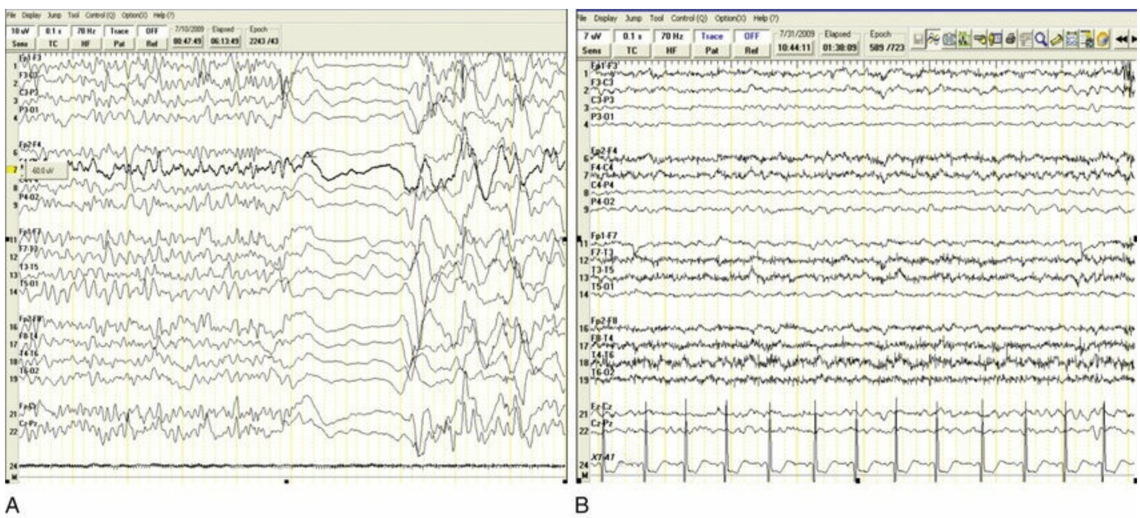

FIG. 62.1 Bipolar EEG montage of a child with a mild static encephalopathy and spasticity, on dialysis as the sequelae of perinatal renal injury, who developed progressive encephalopathy with high amplitude epileptiform discharges (A). Treatment with flumazenil resulted

in immediate improvement in mental status and sustained improvement in the EEG (B), confirming that the accumulation of baclofen in this dialysis-dependent patient was the source of a waxing and waning encephalopathy.

Vital Signs

Therapies that target specific mechanisms of cell injury for acute CNS disease are lacking in adult and pediatric neurocritical care. Nevertheless, the prevention of hyperthermia may significantly reduce secondary neurologic injury. The results of randomized controlled trials of therapeutic hypothermia in children with severe TBI[26,27] and out-of-hospital cardiac arrest[28,29] suggest that early hypothermia, irrespective of ICP, does not improve outcome and in the case of TBI may increase the risk of death.[27,30,31] Despite this observation, the prevention of hyperthermia can be regarded as a safe and effective intervention.[32] Therefore as a general principle for ICU patients with known or suspected CNS injury, fever should be aggressively avoided.

In contrast to the research on adults, there are limited data on the optimum ranges for blood pressure, ICP, and cerebral perfusion pressure (CPP) for children. For adults, there are goal-directed protocols aimed at improving outcome following TBI. The targets of ICP less than 20 mm Hg and CPP above 60 mm Hg are based on a number of studies.[33-37] In contrast, limited data exist for children with TBI.[38,39] Guidelines suggest an ICP threshold of 20 mm Hg for all ages and a CPP threshold of 40 to 65 mm Hg as an age-related continuum.[40] Although children with TBI who are younger than 2 years of age have a high mortality rate compared with older children, no thresholds for ICP or CPP have been established for this age group.[41] Accordingly, blood pressure, temperatures, and oxygenation must be interpreted in the context of the underlying neurologic insult or risk for further injury. As a general principle, hyperthermia with the attendant increased cerebral metabolic demand should be treated aggressively whatever the primary injury.[42,43]

General Physical Exam

An accurate head circumference measurement is essential in infants and young children and should be documented on admission. This may serve as a baseline for following the development of hydrocephalus in the at-risk infant. In older children, an abnormal (large or small) head circumference may be a previously overlooked sign of pathology. In the infant, the open fontanelle should be palpated and the findings on the exam agreed upon in a quiet, resting state. A bulging fontanelle is an important finding of meningeal irritation or increased ICP. Examination of skin for the cardinal features of the phakomatoses may identify café au lait spots characteristic of neurofibromatosis or shagreen patches, hypopigmented macules, and angiomyofibromas characteristic of tuberous sclerosis. The physical findings associated with inflicted trauma deserve particular mention as these may be subtle,[44] including unusual patterns of bruising, blood in the oropharynx, and burn or belt marks.

Importance of Observation in the Neurologic Exam

The elements of the neurologic examination in the PICU constitute the same features of the neurologic exam for noncritically ill patients. The assessment of mental status, cranial nerves, motor function, reflexes, sensation, and cerebellar function must be adapted to each patient, but the structure of the neurologic exam in the PICU is no different from the outpatient examination. If possible, sedating drugs and paralytic agents should be reduced prior to the exam. If this is not feasible, the exam must be interpreted in the context of these confounds.

The assessment of mental status begins with observation. The examiner should first confirm the drugs used for sedation, if any, and recent changes in dosing. It is not possible to give precise dose ranges for typical sedating agents associated with a mental status exam. For commonly used agents in the PICU (midazolam, morphine, fentanyl, dexmedetomidine), the effects of the drug on arousal and responsiveness will vary with the age of the patient, duration of exposure, nature of the neurologic insult, effect of other drugs on metabolism, and genetically determined ability to clear these drugs. This complex set of interactions underscores the importance of experience in the examination of these patients to determine what is an acceptable level of arousal and the need for serial neurologic examinations.

The observations of the nurses and parents should first be solicited. The examiner should enquire about evidence for changes in arousal or awareness, such as spontaneous eye opening, evidence of a sleep-wake cycle, change in activity, or response to interventions such as suctioning. If family members are present, their observations of the patient's response to their presence or voice are important and may represent the first signs of awareness on the part of the patient. It is appropriate to have a family member carry out part of the exam by asking the patient to follow commands, because these young patients are more likely to respond to their family members than to a stranger.

The pattern of breathing rate and rhythm should be observed. Specific patterns may help localize the site of neurologic dysfunction but not the mechanism involved (Table 62.1). The crescendo-decrescendo pattern alternating with periods of apnea, characteristic of Cheyne-Stokes respiration, may be due to dysfunction of the cerebral hemispheres, thalamus, or hypothalamus with preserved brain stem function, but it can also be found in patients with congestive heart failure or primary respiratory disease. Similarly, the sustained, deep breathing pattern of central neurogenic hyperventilation may be due to structural injury to the midbrain, sepsis, pulmonary disease, or compensated metabolic acidosis.

TABLE 62.1

Approach to the Intensive Care Unit Neurologic Examination: Localization and Mechanism

Exam Finding	Structural-Vascular Insult	Toxic-Metabolic
Consciousness	Stays at same level or deteriorates	Waxes and wanes, milder impairment; toxins may cause progressive decline
Respiration	Cheyne-Stokes (crescendo-decrescendo alternating with apnea): loss of cerebral, thalamic, or hypothalamic control of breathing	Cheyne-Stokes: congestive heart failure; primary respiratory disease
	Neurogenic hyperventilation (sustained, rapid, deep breathing): midbrain disease	Neurogenic hyperventilation: metabolic acidosis; sepsis; liver failure
	Gasping respiration (irregularly irregular): dysfunction	Gasping respiration: intoxication (opiates,

	of lower brain stem or medulla	barbiturates); hypothyroidism)
Funduscopy	Papilledema due to increased intracranial pressure	Papilledema does not occur except in hypertensive encephalopathy, lead intoxication, hypoparathyroidism
Eye position	Versive deviation	Versive deviation
	Stroke ipsilateral to direction of deviation	Seizure contralateral to direction of deviation
	Retraction or convergence nystagmus Midbrain	
	Ocular bobbing Pons Intranuclear ophthalmoplegia Pons or midbrain Oculomotor nerve palsy Midbrain or herniation Skew gaze Brain stem	No extraocular movement with preserved pupil reactivity Toxin
Pupil reactivity	Small reactive Thalamus, hypothalamus Midposition, fixed Midbrain Pinpoint, reactive Pons Small, combined with ptosis Horner, lateral medulla, sympathetic chain	Small reactive
	Large, fixed	Large, fixed
	Oculomotor nerve, tectum	Botulism, opthalmic drops
Eye movements	If asymmetric, likely structural	Roving more common with metabolic derangements
	Oculomotor nerve palsy Midbrain or herniation syndrome Abducens nerve palsy Unreliable localization Internuclear ophthalmoplegia Midbrain or pons Disconjugate or skew gaze Brain stem Absent vertical and retained horizontal movement Midbrain Absent horizontal and retained vertical movements Pons	Absence of all movement with intact pupil light reflex
Adventitious movements	Posturing; sign of herniation Myoclonus following severe cerebral ischemia	Restlessness, tremor, spasm, myoclonus, chorea, akathisia
Muscle tone	Asymmetric; increased, normal, or decreased	Symmetric; normal or decreased

The conventional neurologic examination proceeds from mental status, cranial nerves, motor (bulk, tone, and strength), reflexes, and sensation to cerebellar exam and gait. In children and in the PICU in particular, the exam must be based on good observation and is often best performed out of sequence. It is easier to assess tone and reflexes in the asleep, relaxed patient before waking the patient up to assess mental status. Although the exam is discussed in the standard order presented next, it may be more informative to begin the hands-on part of the exam with an assessment of tone and reflexes. Once the patient is awake and agitated, subtle asymmetries of tone and reflexes, which may be key findings of the exam, may be obscured.

First, the child is observed. The state of arousal (awake, asleep), responsiveness, (interactive, verbal, nonresponsive), position (tone, asymmetry of limb position), and movement (purposeful, spontaneous, dystonic, choreic, asymmetry of movement) can all be reliably assessed by observation. In a nonintubated, nonsedated patient, the examiner may proceed directly with a standard mental status exam adjusted for age. In the young child who is able to cooperate, the specific cognitive and language skills expected for age can be assessed (Table 62.2).

TABLE 62.2

Age-Dependent Motor and Language Patterns

Age (months)	Motor	Language
15	Walks alone; crawls up stairs	Jargon; follows simple commands
18	Runs; sits on chair; walks up stairs with hand held	10 words; names pictures; identifies body parts
24	Runs well; walks up and down stairs	Three-word sentences
30	Jumps	Refers to self as "I"
36	Stands on one foot; goes up stairs with alternating feet	Knows age and gender; counts three objects
48	Hops on one foot; throws ball	Tells a story
60	Skips	Names four colors; repeats 10-syllable sentences

Assessment of Level of Consciousness and Mental Status

For children with depressed consciousness, the precise stimulus required to elicit a response and the nature of this response should be specified. It is not helpful to describe the patient as lethargic or obtunded. First, the child is called by name to determine if there is a response. If this is not effective, the examiner may ask a family member to speak to the child. Next, the stimulus is increased. It is most helpful to describe the patient's response to specific stimuli and to use the same stimuli for serial examinations. The Glasgow Coma Scale score, though of limited use in preverbal children (Table 62.3), is a rapid, quantitative measure. If the patient's eyes open in response to someone's voice, the response to commands is tested next. This step is discussed in more detail later, but the commands should be increased in complexity from one to two or three steps. If there is no response to voice, a painful stimulus is next applied. Note that in patients with sensory deficits due to neuropathy, spinal cord, or CNS lesions or with focal limb weakness, the extremity or dermatome selected for testing should have intact sensory or motor function. In the sedated or severely impaired patient, the response may constitute only an increase in heart rate. It is important that the stimulus and the specific response, rather than vague descriptors *(lethargic, drowsy, sleepy)*, are documented, as this information will be more helpful in assessing serial examinations. The rate of sedating drugs or recent administration of sedating drugs should be documented with this exam.

TABLE 62.3

Glasgow Coma Scale

Activity	Best Response	Score
Eye opening	Spontaneous	4
	To command	3
	To pain	2
	None	1
Verbal	Oriented	5
	Confused	4
	Inappropriate words	3
	Incomprehensible sounds	2
	None	1
Motor response	Obeys commands	6
	Localizes pain	5

	Withdraws to pain	4
	Abnormal flexion to pain	3
	Abnormal extension	2
	None	1
Total		3-15

The assessment of higher cognitive function and the early recognition of compromise of cognitive function are always challenges when evaluating young children. In the ICU where the additional confounds of sedation, other organ dysfunction, sleep disturbance, and anxiety must be accounted for, this evaluation is somewhat more challenging. Of course, this is usually the most important component of the exam, and the technologies used for neurologic monitoring in the ICU (imaging, EEG, NIRS, microdialysis, optic nerve sheath diameter, tissue oxygenation) all serve the goal of the bedside exam—to detect compromise of cerebral function so as to enable directed therapeutic intervention.

In the older, awake child, a complete mental status exam can be performed. This must be adjusted for age (Table 62.2) but should include an assessment of language (fluency and comprehension) including the ability to name, repeat, write, read, and respond to written commands. Simple mathematical problems should be adjusted to the child's age-dependent ability. Praxis can be assessed quickly, even in the PICU, by asking the child to demonstrate learned behaviors (brush your teeth, brush your hair). Other components of the mental status exam, including memory, fund of knowledge, and reasoning, can be assessed by holding a conversation with the patient.

Most important, the examiner needs to have an appropriate index of suspicion for subtle neurologic deficits of attention, memory, praxis, language comprehension, and reading comprehension, which may be the early sign of new neurologic injury. This is particularly true for patients with metabolic (often liver or renal failure), infectious, or iatrogenic (sedation, immunophilins) risk factors for CNS dysfunction and may easily be missed if not specifically investigated. Again, serial examinations by clinicians familiar with the patient's assessment while sedated are the key to the reliable detection of new deficits of higher cortical function in the ICU.

Funduscopic Examination

Examination of the fundi may reveal hemorrhages or papilledema. Hemorrhages indicate either acute subarachnoid or subdural hemorrhage, cranial trauma from a direct blow or shaking injury, or malignant hypertension. Papilledema indicates raised ICP from any cause. Usually papilledema develops hours after the onset of the elevated ICP. Acute severe increases, however, as with subarachnoid hemorrhage (SAH) from a ruptured saccular aneurysm, can result in almost instantaneous papilledema. Sometimes papilledema never develops, despite prolonged severe elevations of ICP.

Cranial Nerve Examination

The pupillary reaction to light is abolished only by structural damage to the midbrain or third cranial nerve. Loss of the pupillary reflexes is always an ominous finding. Preservation of pupillary reflexes in the presence of deep coma suggests a metabolic-toxic cause. The interpretation of the patterns of pupil reactivity is

summarized in Table 62.1.

Pupil size and light response are quantifiable measures of brain stem and autonomic nervous system function, and the absence of pupil reactivity is a poor prognostic sign after TBI or cardiac arrest. To provide a precise measure of pupil size and speed of contraction and relaxation, a portable handheld device (pupillometer) illuminates the eye with an infrared light (850 nm) while acquiring images for analysis. The data (pupil size, rate of contraction, and relaxation) are stored on the device and can be downloaded to a computer. In a study of healthy volunteers and adult patients with TBI and ICP monitors in place, a discrepancy in pupil size of more than 0.5 mm appeared to be associated with ICP above 20 mm Hg.[45] In a study of 134 adults with TBI, aneurysmal SAH or intracerebral hemorrhage pupil reactivity decreased an average of 16 hours before the peak ICP was reached.[46] There are as yet no comparable data for pediatric neurotrauma. In children, no association of age and pupil size has been reported, but the maximum diameter and velocity of constriction are affected by sedation.[47]

Eye movements are assessed first by observation and then elicited in the patient with depressed mental status by application of the doll's head maneuver (oculocephalic response) or cold caloric stimulation (oculovestibular response). The interpretation of eye movements and position is summarized in Table 62.1. In general, coma produced by metabolic dysfunction is initially associated with roving, disconjugate movement and may progress to the cessation of movement. Cold caloric stimulation produces nystagmus with the rapid phase contralateral to the ear that has been stimulated. This rapid phase is the equivalent of saccadic eye movements and indicates intact functioning of the cerebral cortex. The ears are irrigated separately several minutes apart. In comatose patients, the fast, “corrective” phase of nystagmus is lost and the eyes are tonically deflected to the side irrigated with cold water or away from the side irrigated with warm water. These vestibuloocular responses are lost or disrupted in brain stem lesions. Versive eye deviation is a common finding suspicious for seizures. In this case, the eye deviation is contralateral to the hemisphere with the ictal focus. Alternatively, stroke in the ipsilateral hemisphere may also produce versive eye deviation toward the side of the stroke.

An abnormal corneal reflex may indicate either fifth nerve afferent disease (ipsilateral stimulation results in neither a direct nor consensual eye blink) or seventh nerve efferent disease (ipsilateral stimulation results in a brisk consensual but no direct response).

Unilateral weakness of eye closure, forehead movement, and mouth movement indicates peripheral seventh cranial nerve palsy, whereas failure to move only the mouth with preservation of upper face movements indicates a central corticospinal tract lesion rostral to the pons. Facial weakness may be noted during grimacing while responses to painful stimuli are evaluated. Voluntary pharyngeal and laryngeal control is tested by asking the patient to speak and say “ah.” In the absence of voluntary movement, a hypoactive gag indicates medullary or vagal dysfunction and a hyperactive gag indicates interruption of corticospinal inhibition to the medulla. In a comatose patient or one whose consciousness is rapidly sinking, one must quickly determine whether the patient is experiencing raised ICP. Papilledema or third cranial nerve palsy are strong evidence of elevated ICP.

Approach to the Motor Exam

In the comatose or obtunded patient, asymmetry of resting tone or spontaneous movement is a simple sign of paresis, which can be detected by first observing the patient. In children this is particularly important, as a subtle weakness may not be apparent once the child is more awake and resisting cooperation with the exam. An externally rotated, partly flexed abducted leg may indicate an ipsilateral hemiparesis due to an upper motor neuron lesion. Facial weakness should also be first evaluated by observation before attempting formal testing (often impossible or unreliable in young, anxious, or sedated children). Signs of facial weakness at rest may include a widened palpebral fissure, diminished nasolabial fold, or flattened corner of the mouth. The examiner should next attend to the initial movement of the face, either spontaneously or in response to a noxious stimulus. Subtle weakness may be apparent only in a delayed response to these stimuli.

Weakness may be due to lesions at any level of the neuraxis. The goal of the examination of the weak patient is to identify the pattern of weakness as that of the upper or lower motor neuron and thereby identify the most likely mechanisms. The upper motor neuron (UMN) comprises the corticospinal tract and its neurons. The corticospinal tract begins in the motor and premotor cortex anterior to the central sulcus, descends through the central white matter of the cerebral hemispheres, decussates in the lower medulla, and terminates on the anterior horn cells or interneurons closely associated with the anterior horn cells. The innervation of muscles that control movement of the jaw, pharynx, larynx, upper half of the face, neck, thorax, and abdomen is derived from both cerebral hemispheres. Consequently, unilateral cerebral lesions lead only to weakness of the contralateral limbs and lower face. The lower motor neuron (LMN) comprises the anterior horn cells, motor roots, peripheral nerves, pre- and postsynaptic components of the neuromuscular junction, and the muscles receiving this innervation. Stereotyped reflex movements may be present despite spinal cord injury because local spinal reflexes below the level of the lesion coordinate these responses. In contrast, movement is absent following injury to the LMN because it is the final common pathway producing muscle activity. If the patient is not able to cooperate with a complete exam testing all muscle groups, in addition to observing for asymmetric posture, the observation of facial movement; testing for neck flexion, grip strength, and pronator drift; and counting the duration (up to 10 seconds) that the patient can maintain a straight leg raise are efficient means of assessment.

A number of key findings on the pattern of weakness can distinguish between UMN and LMN injury, chronic and acute injury, and neuropathy and neuromuscular disorders including ICU-acquired paresis, myasthenia gravis, and Guillain-Barré syndrome (GBS). Acute UMN lesions result in a hypotonic or flaccid pattern of weakness, and in the legs they may be associated with the Babinski sign. In contrast, chronic UMN injury results in a hypertonic limb with associated hyperreflexia. An LMN pattern of weakness is more likely to be associated with a decrease in muscle tone and bulk and decreased or absent reflexes. In general, proximal weakness suggests a myopathic process, whereas a distal pattern of weakness suggests a neuropathy. The precise incidence of ICU-acquired weakness (ICU-AW) is uncertain in children.[9] In a study of the incidence of weakness in 830 critically ill children, only 1.7% had generalized weakness.[48] This is lower than the

incidence of ICU-AW in adults.[49] Extensive data from adult studies have identified ICU-AW—manifest as a variable combination of weakness, muscle atrophy, hyporeflexia, and sensory deficits—as a common cause of failure of extubation with a high incidence of long-term morbidity. The contribution of the risk factors in adults (sepsis, hyperosmolarity, neuromuscular blockage, prolonged ventilation, and corticosteroids) to pediatric ICU-AW is not known. ICU-AW is primarily a clinical diagnosis, although nerve conduction and electromyography studies may be confirmatory. Management, particularly in children, is empirical, but this disorder should be suspected in any critically ill child with diminished reflexes and new weakness or difficulty with extubation.

The two most common neuromuscular disorders that require ICU level of care in children are GBS and myasthenia gravis (MG) (discussed in Chapter 71). For patients with known myasthenia admitted to the ICU in crisis, it is essential to note the timing of anticholinesterase treatment and the timing of the neurologic exam in relation to each evaluation of strength. In general, testing should be performed at the nadir of weakness prior to each treatment. This is the only reliable way to detect a decline in strength in these patients. In contrast to GBS, the progression to respiratory failure in MG may be arrested by noninvasive ventilator support with bilevel positive airway pressure (BiPAP). Muscle fatigue in MG is reversible with a combination of anticholinesterase treatment and BiPAP, which may prevent the need for intubation. In the case of GBS, patients who cannot walk unaided should be treated with intravenous immunoglobulin (IVIG).[50] Neither GBS nor myasthenia should alter pupil reactivity. In this case, if the pupils are slow to react or do not react in a weak infant, the diagnosis of botulism should be considered.[51]

Posturing, due to increased ICP, should be distinguished from abnormal movements including chorea and dystonia. Decorticate posturing consists of adduction and stiff extension of the legs, flexion and supination of the arms, and fisting of the hands. This occurs when the midbrain and red nucleus control body posture without inhibition by diencephalon, basal ganglia, and cerebral cortex. Decerebrate posturing consists of stiff extension of legs, arms, trunk, and head with hyperpronation of lower arms and plantar flexion of the feet. This indicates pontine and vestibular nucleus control of posture without inhibition from more rostral structures. Lesions below the level of vestibular nuclei lead to flaccidity and abolition of all postures and movements. These movements should be distinguished from dystonia or chorea, which may be seen as side effects of medications, the sequelae of basal ganglia injury, or metabolic or neurotransmitter disorders.

Reflexes

Reflexes may be absent in critically ill children, wax and wane during the course of the day, or be elicited by some examiners but not others. This variability can be diminished by performing the exam when the child is in a quiet, resting state and by focusing on key reflexes. In general, the purpose of the exam is to determine whether there are changes in intensity (a reduction or an increase), symmetry, or the development of pathologic reflexes.

At a minimum, reflexes to be tested include the tendon jerks in the upper (if available) and lower extremities and the Babinski sign (dorsiflexion of the great toe, sometimes accompanied by fanning of the toes in response to stimulation of the

lateral plantar aspect of the foot) as the cardinal screening test for intact functioning of the pyramidal system. If an extensor plantar reflex is present, this reflects injury along the corticospinal tract. The rest of the neurologic exam is then used to identify the level at which this injury is present. A number of other techniques (Chaddock, Oppenheim, Gordon, Strumpell, Moniz, Gonda-Allen) may be used[52] to elicit the extensor response, but the Babinski is the most reliable.

In patients with decreased or altered mental status, frontal lobe release signs may be tested. These signs reflect diffuse cerebral dysfunction or injury. The grasp reflex involves the patient reflexively gripping the examiner's finger or hand as the palm is brushed. The palmomental reflex is elicited by scratching the thenar eminence and observing for twitching of ipsilateral lower jaw muscles. The snout reflex is elicited by tapping on the mouth and producing puckering of the lips. To elicit the rooting reflex, the mouth is lightly scratched, which causes the patient to turn so as to align the mouth with the finger. The glabellar reflex is elicited by tapping the forehead in the midline (this is done from above the head so as not to confuse the response with the reflex response to visual threat) and observing for repeated blinking each time the forehead above the bridge of the nose is tapped.

Cerebellar Function and Gait Evaluation

Normal coordination requires that both muscle strength and proprioception are intact. The interpretation of the cerebellar exam testing should be done with these systems already evaluated. Abnormal eye movements including dysmetria (overshoots of the target or a series of ratchet-like undershooting movements to reach the target when the eyes are rapidly brought from fixation on one object to another), gaze-evoked or downbeat nystagmus, or speech (slow, impaired prosody, distorted consonants or vowels, mutism) may be the only observable manifestations of cerebellar dysfunction in a patient who is sedated or too weak to cooperate with the remainder of the exam. Truncal ataxia can be detected by sitting the patient up in the bed. If possible, gait should be evaluated and observed for a widened base and the ability to perform rapid turns while maintaining normal balance.

Sensory Examination

Even in the alert patient, this component of the neurologic examination is the least reliable and the first to be discarded if necessary. Of the components of this exam, vibration and joint position sense are the most sensitive. In the sedated patient or patient with a depressed level of consciousness, sensation testing may need to be limited to noting withdrawal or flexion of the stimulated limb or an increase in heart rate. In the cooperative patient, temperature sensation can be evaluated using a tuning fork, which should feel cool. The examiner should be particularly alert to detecting a level at which sensation (pain, temperature, light touch) is lost or diminished in patients with spinal cord injury, TBI (with unrecognized cord injury), or inflammatory (transverse myelitis) or demyelinating disorders of childhood (acute demyelinating encephalomyelitis, multiple sclerosis), which may involve the spinal cord. In patients with cerebral injury, a lack of response to sensory testing should be distinguished from neglect.

Abnormal Movements or Altered Sensorium in the Child With Static Encephalopathy

This is a common issue in the PICU, often because of concern that the patient may be seizing, and may prompt obtaining additional imaging or EEGs because these children have primary neurologic disorders. A stepwise approach is helpful. A limited behavioral repertoire in these patients may mask subtle medical or surgical problems. For a neurologist, this evaluation should also present an opportunity to revisit the diagnosis of cerebral palsy or static encephalopathy, which may be obscuring a diagnosable (and perhaps treatable) disorder such as dopa-responsive dystonia. In such cases, in addition to (often instead of) monitoring for neurologic injury, evaluations should consider other etiologies including pain from unrecognized trauma, hip subluxation, long bone fractures, constipation, urinary infection or retention, volvulus, inguinal hernia, corneal abrasion, otitis media, dental pathology, gastric distention, or bowel adhesions. A systematic approach to evaluation of spells in these patients is essential to avoid missing treatable medical conditions seen in patients with chronic neurologic disorders.

Distinguishing Functional Deficits From Nonorganic Pathology in the Pediatric Intensive Care Unit

Not all neurologic deficits in the PICU are organic. Conversion disorders also occur in critically ill patients or result in patients being admitted to the PICU. In the latter case, this is most often due to a suspicion for nonepileptiform seizures. A number of features of the examination and history may help make this distinction (Table 62.4). In general, and particularly in infants, the eyes are open during a seizure. In one series,[53] over 90% of cases with electrographically confirmed seizures occurred with eye opening. The eyes may look straight ahead, deviate to one side contralateral to the hemisphere from which the seizures originate, or exhibit only nystagmus. Seizures are typically a positive phenomenon and will have movement associated with them unless there has been injury to the corticospinal tracts resulting in a paretic limb. Other features of the exam, or description of the spells including stereotypy, crescendo-decrescendo behavior, or the presence of automatisms, may help to distinguish ictal and nonictal behavior. In most cases, video EEG monitoring is the most definitive means of distinguishing ictal from nonictal events.

TABLE 62.4

Clinical Features of Seizures and Nonepileptic Spells

	Seizures	Nonepileptic Spells
Eyes	Open	Closed
Automatisms	Common	Rare
Stereotypical behavior	Common	Rare
Onset is gradual	Rare	Common
Waxing and waning course	Rare	Common
Thrashing movements	Rare	Common

Even in the PICU, the examiner should remember that functional deficits may be detectible, and a number of motor signs may help identify the origin of functional symptoms. Given the complex pathophysiology of many critically patients and the

multiple potential mechanisms of neurologic injury, the diagnosis of a functional neurologic deficit should be made only after a thorough evaluation for organic causes. Although this is uncommon in the PICU, a functional etiology should not be overlooked, and early identification may minimize diagnostic testing and unnecessary or high-risk treatment. A number of elements of the physical exam may help one to distinguish between organic and functional neurologic deficits.[54] An inconsistent examination may be the first clue, such as that observed in the patient with apparent weakness during bedside strength testing who can change position during sleep or who can walk despite apparent paresis on bedside testing. These observations can help in the assessment of children with weakness thought to be due to a neuromuscular disease. After first observing for inconsistency, the most useful test for functional weakness is the Hoover sign. This test relies on the principle that when flexing one's hip the natural accompanying movement is to extend the contralateral hip.[54] With the patient supine, the examiner places one hand on the weak leg and the other hand under the ankle of the strong leg. The patient is then asked to perform a straight leg raise of the healthy limb. In a functional pattern of weakness, the examiner will feel no downward pressure from the good leg because no effort is being applied to raise the ostensibly weak leg. Other tests include the *arm drop,* in which a paretic or plegic arm is dropped over the patient's face, and a sensory exam that shows exact splitting of sensory or vibration deficits in the midline. A number of functional gait disturbances are also characteristic, including a monoplegic dragging gait (the whole limb is dragged without the circumduction present in pyramidal hemiparesis), a *walking on ice* pattern, excessive slowness, or sudden buckling at the knees with recovery. Of these, none are definitively diagnostic of a functional pathology, and in children in particular they must be interpreted with caution. Importantly, functional and organic deficits may coexist.

Anti–*N*-methyl-D-aspartate (NMDA) receptor encephalitis is a recently discovered class of disorder that may mimic psychiatric disorders such as depression, catatonia, or viral encephalitis and has important complications including nonconvulsive seizures and autonomic dysfunction requiring ICU care.[55,56] This disorder is one of a family of antibody-associated inflammatory brain diseases in children.[57] Patients may at first appear to have a functional exam before other characteristic features including a movement disorder, sleep disturbance, seizures, and autonomic dysfunction emerge.[58] Early recognition and the initiation of immunosuppression with steroids, IVIG, or plasmapheresis are the keys to improving long-term outcome and reducing complications including cardiac arrhythmia.[59]

Goals of the Neurologic Examination in the Pediatric Intensive Care Unit

At the conclusion of the neurologic examination in the ICU, the examiner should be able to identify the locations of neurologic dysfunction at the very least in terms of injury to gray (encephalopathy, seizures, neglect, aphasia) or white (weakness, spasticity) matter, posterior circulation (brain stem dysfunction, cranial nerve palsy with contralateral weakness), the presence of signs of increased ICP, spinal cord (sensory or motor level), peripheral nerve (decreased or absent reflexes), neuromuscular junction, or muscle injury. This should be established either as the

baseline exam or compared to previous examinations and therefore assessed as progressing, improving, or stable. Next, the mechanism producing this injury should be assessed and ranked in order of likelihood. In general, this will involve primary neurologic insult such as TBI, stroke, CNS infection, neurodegenerative disease, autoimmune or parainfectious processes, or the complications of other common pediatric disorders requiring ICU care including sepsis, congenital heart disease, liver failure, organ transplant, diabetic ketoacidosis (DKA), renal disease and dialysis, status epilepticus or iatrogenic complications of commonly used drugs such as immunophilins, or intrathecal chemotherapy.

The goal of the examiner is to combine data from the history, presenting signs, and physical examination (which may need to involve only observing the patient) in order to develop a differential diagnosis for both the site of injury and the mechanism. These mechanisms will involve one or more common etiologies including vascular origins (ischemia, hemorrhage, large or small vessel, arterial or venous, artery-to-artery or cardioembolic); metabolic origins (iatrogenic [often abnormalities of sodium, glucose, or ammonia] or the first presentation of a metabolic disorder); autoimmune origins (CNS lupus, autoimmune encephalopathies and epilepsies); parainfectious origins (ADEM); iatrogenic origins (sedation, neuromuscular blockade, immunophilins); toxic origins (drugs of abuse, drug metabolite accumulation in liver or renal failure); and infectious origins (systemic infection with CNS involvement, meningitis or encephalitis, or reactivation of a latent CNS infection in the immune-suppressed patient).

Based on the postulated location of the insult, stability of the neurologic examination, mechanism of injury, and risk for progression of neurologic injury, the monitoring modalities can then be selected based on the need to establish a diagnosis, monitor for secondary neurologic injury, or both.

Neuroimaging

Computerized tomography (CT) and magnetic resonance imaging (MRI) each have specific advantages (Table 62.5) and should be selected for specific purposes (discussed in Chapter 63). CT can be performed quickly and is a sensitive means of detecting cerebral edema or blood. CT is relatively insensitive to acute ischemic injury and does not provide sufficient resolution in the posterior fossa, where lesions may be missed. Diagnostic CT scans should be performed first without contrast and then with contrast (if not contraindicated). White (dense) lesions on the noncontrast study are either hemorrhage or calcification. In most patients in the PICU, these white areas represent hemorrhage. Contrast enhancement indicates either local breakdown of the blood-brain barrier or excess vascularity and is associated with neoplasms, infections, inflammatory lesions, and subacute stroke.

TABLE 62.5

Neuroimaging Advantages and Limitations

	Plain CT	MRI	CT Angiogram	MR Angiogram	Conventional Angiogram
Purpose	Detection of edema or blood	Higher anatomic resolution; DWI can detect early	Evaluate large cerebral arteries	Evaluate large cerebral arteries	Gold standard. Obtain if CTA or MRA negative and dissection or

		ischemic changes			vasculitis suspected
Advantage	Fast, widely available	DWI can detect acute ischemia	Better detection of intracranial stenosis and occlusion than MRA	Detects large vessel arteriopathy	Most sensitive to small vessel disease, dissection, vasculitis
Limitations	May not detect acute ischemia; insensitive to posterior fossa lesions	Less available on emergent basis; patient may need sedation	Large radiation dose	Not a measure of flow; not sensitive to small vessel disease	1% risk of complication

MRI stimulates tissue with a specific radiofrequency pulse, after which the tissue returns to its preexcited state by processes known as T_1 or T_2 relaxation. In the T_1 sequences, which measure T_1 relaxation, cerebrospinal fluid (CSF) appears dark, and it appears white in the T_2 sequences. Gradient echo (GRE) sequences are most sensitive for detecting hemorrhage on MRI. In these sequences blood appears dark early (4 to 6 hours) after hemorrhage and remains dark in all later stages of hemorrhage. Small infarcts, infections, inflammatory areas, and demyelinating plaques are more readily detected on MRI than on CT. Fluid-attenuated inversion recovery (FLAIR) imaging uses T_2-weighted sequences in which CSF appears dark. For the detection of ischemic conditions, diffusion-weighted images (DWI) are more sensitive than CT scan in the detection of acute cytotoxic edema. This sequence can identify acute ischemic strokes as bright lesions within minutes of their occurrence (Fig. 62.2A). Bright lesions on DWI indicate a restriction in the movement of water and thus an increased water content of that region. The degree of water proton mobility is quantified by the apparent diffusion coefficient (ADC). On ADC maps, areas of restricted diffusion appear as hypointense (dark) (Fig. 62.2B). The reason for early decline in ADC is thought to be cytotoxic edema as a result of cellular energy failure causing a loss of ion homeostasis and a subsequent shift of water to the intracellular compartment. Not all restricted diffusion is ischemic in origin (Figs. 62.2C and D) and may instead be associated with inflammation (infection, demyelination) or metabolic derangement as in the case shown, an example of a metabolic stroke due to partial ornithine transcarbamylase deficiency mimicking a watershed stroke. Magnetic resonance angiography (MRA) and magnetic resonance venography (MRV) are used to detect vascular occlusions in large- and medium-size vessels in the head and neck, cerebral aneurysms larger than 5 mm, and arterial dissection (detects the presence of methemoglobin in the false lumen within the vessel wall). If MRA or CT angiography (CTA) is negative and a dissection is suspected, a conventional angiogram should be obtained. Similarly, if small vessel arteriopathy or vasculitis is suspected and MRA or CTA is negative, conventional angiography should also be obtained.

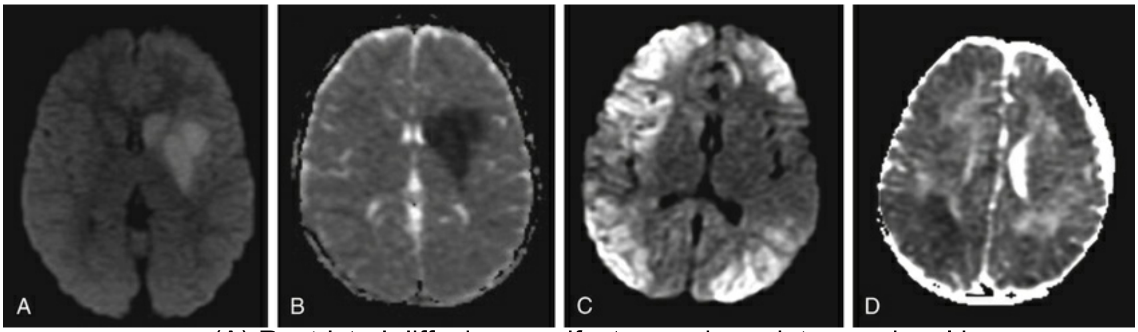

FIG. 62.2 (A) Restricted diffusion manifests as a hyperintense signal in the left caudate, putamen, and globus pallidus in a 5-year-old girl with an acute onset of right-sided weakness due to carotid dissection after a fall. (B) Dark signal on the ADC map supports the mechanism as ischemic in this clinical context. (C) Restricted diffusion in a watershed pattern in a previously healthy 1-year-old child with partial ornithine transcarbamylase deficiency and (D) associated reduced signal in the corresponding ADC map. In this case the mechanism is due to metabolic compromise, not ischemia.

For traumatic diffuse axonal injury (DAI) in particular following TBI, diffusion tensor imaging (DTI) has emerged as a promising means for detecting injury. DAI is thought to be a major contributor to cognitive dysfunction ranging from cognitive difficulty to coma following TBI,[60-63] but it is difficult to diagnose or characterize noninvasively. The cellular mechanisms involved in the long-term sequelae of TBI in children lead to a compromise of neuronal metabolism, perfusion, and axonal function, all components of the neurovascular bundle.[64] Advances in imaging technology using DTI MRI have allowed early detection of axonal injury in patients following TBI and have linked cognitive disability in these patients to white matter signal changes.[62,65-67]

The effect of therapeutic hypothermia on the radiographic evolution of restricted diffusion on DWI in children following cerebral ischemia is not known. In practice, this means that as the use of hypothermia is extended from the asphyxiated newborn to children with cardiac arrest[68] and TBI, the results of DWI studies may potentially underestimate the degree of ischemia if obtained during or close to treatment with hypothermia. In a retrospective Korean study of adults (lowest age 18 years) with cardiac arrested treated with hypothermia, positive DWI imaging in the first week after arrest was significantly associated with poor outcome (OR, 58.2; 95% CI, 13–255).[69]

As transport of the critically ill child, the increased duration of the scan (compared to CT) and the availability of the scanner are important in the decision to obtain MRI. One approach is to streamline the use of MRI by only obtaining sequences specific to the insult being evaluated. Thus for suspected ischemia, only DWI and ADC sequences are obtained; for hemorrhage, GRE; hydrocephalus, MR of the ventricles; sinus thrombosis, MR venogram; dissection or large vessel vasculitis, MR angiogram; metabolic disease, MR spectroscopy; and for cortical dysplasia in epilepsy patients, standard MRI. This means that a patient admitted with suspected stroke can complete a study (MR ventricles and DWI) in a much shorter time window than is otherwise required and the most important initial question (presence or absence of ischemia) can be addressed so that therapy can be adjusted.

In children in particular, neuroimaging cannot be used as the definitive measure

of the presence or absence of intracranial hypertension. Rather, the examiner must rely on a combination of assessment of risk factors and clinical examination (including changes in the examination) combined with imaging findings (which may be unremarkable).

Intracranial Pressure Monitoring

The most common indication for ICP monitoring in critically ill children is TBI (discussed in Chapters 66 and 119), in which the measurement of ICP serves to direct therapy with the goal of preventing the secondary complications of TBI resulting from cerebral hypoperfusion or metabolic stress. For children with severe TBI, a CPP between 40 and 65 mm Hg is recommended,[40] and a CPP of 60 to 70 mm Hg is recommended for adolescents.[70,71] Optimal CPP levels for children under 2 years of age have not been established. The lack of age-specific CPP thresholds for severe TBI was addressed in a study using an online Internet database, TBI-trac containing data from trauma centers in New York State.[72] The investigators measured the survival rates and relative risks of mortality for 317 children with severe TBI based on predefined, age-specific higher and low CPP thresholds (60 and 50 mm Hg for children 12 years old or older, 50 and 35 mm Hg for those 6–11 years, and 40 and 30 mm Hg for those 0–5 years). The results supported age-specific CPP targets above 50 or 60 mm Hg in adults, above 50 mm Hg in 6- to 17-year-olds, and above 40 mm Hg in 0- to 5-year-olds. The authors assumed that the zero points for the ICP and blood pressure transducers were uniform across institutions and that both were set at the level of the foramen of Monro. However, some patients may have had the head of the bed elevated, and this may have led to variability in the calculation of CPP. Because the threshold for increased mortality in this analysis was based on the lowest CPP a patient experienced, comparing these results with the dose of abnormal ICP or CPP as proposed by other investigators is not possible.[30,73]

A multicenter study of 324 patients ages 13 years or older with severe TBI carried out in Bolivia and Ecuador called into question the benefit of monitoring ICP.[74] In this study, patients were randomly assigned to either guidelines-based management using a protocol in which treatment was based on imaging and clinical examination or a protocol for monitoring ICP. There was no significant difference in the primary outcome (a composite measure of functional and cognitive status) or in 6-month mortality between groups; however, non-ICP monitored patients received more ICP-directed therapies than the monitored group. The extent to which these results apply to North American and European practice is uncertain.

The benefits and complications of ICP monitoring are unproven for other conditions in which ICP may be increased (eg, DKA, meningitis, metabolic disorders, ALF, stroke, brain tumors, cardiac arrest, hypoxic-ischemic encephalopathy, drowning). Similarly, data on treatment goals of ICP or CPP specific to each insult are lacking.

In pediatric ALF, neurologic morbidity is a major determinant of outcome[75,76] with compromise of astrocyte metabolism postulated as a pivotal mechanism in the development of cerebral edema associated with hepatic encephalopathy.[77] A single-center retrospective review reported on 14 children with ALF who underwent ICP monitoring of which only one developed a small intracranial hemorrhage,[78] suggesting that invasive ICP monitoring can be performed safely in children with

ALF. ICP monitoring is used in approximately 7% of patients with meningitis,[79] and mortality is higher in patients with meningitis and a mean CPP of less than 50 mm Hg.[80] Results of a randomized controlled trial of 110 comatose children with acute CNS infection and raised ICP suggest that a CPP goal is superior to the ICP goal.[81] This study compared a goal CPP of ≥60 mm Hg to a goal ICP of <20 mm Hg,[81,81] and 90-day mortality was significantly lower (18.2%) in the CPP group compared to the ICP group (38.2%; RR = 2.1). This treatment resulted in systolic blood pressures in the 95th percentile for age.

In two children with DKA and cerebral edema, invasive multimodal neuromonitoring, combining ICP and brain tissue oxygen ($PbtO_2$) monitoring, was used to guide therapy.[82] The authors selected a target ICP of ≤20 mm Hg and CPP ≥60 mm Hg, with $PbtO_2$ ≥20 mm Hg. Despite achieving these values for ICP and CPP, there were periods when $PbtO_2$ was below the target value. The study provides a precedent for combining ICP-directed therapy linked to optimizing cerebral metabolism. Whether this approach reduces the neurologic complications of DKA-associated cerebral edema is not known.

In sum, although there is potential for the use of ICP monitoring to direct management of other pediatric CNS injuries beyond severe TBI, there are insufficient data at present to justify its use as a standard of care. Nevertheless, precedent from these and other reports suggests that its use in selected patients may be safe and provide meaningful data to direct care of the injured brain.[83,84]

Electroencephalography Monitoring

The importance of the EEG as a monitoring tool in the PICU derives both from its role in the detection of electrographic seizures and from its potential to identify treatable secondary insults in the critically ill patient. In a full montage, 20 scalp electrodes are placed over the skull to record the electrical activity of the surface of the brain. In general, the EEG is used to detect seizures, electrographic activity alone (nonconvulsive seizures), epileptiform activity, focal slowing, or discharges. Until recently, the use of continuous EEG (cEEG) in pediatric critical care was hampered by a lack of availability, delays in timely interpretation of the EEG tracing, and the absence of data to show that treating seizures in some critically ill populations improves outcome. There is now greater availability of this technology in many PICUs,[13,85] in recognition of both the incidence of seizures[86,87] and data showing the impact[88-90] seizures can have on the long-term outcome from critical illness in children.[88-91]

Consensus criteria for the use of EEG in the ICU have been established.[92,93] cEEG is indicated for the detection of NCS (eg, in the patient not awakening after status epilepticus or the paralyzed sedated patient), for the detection of ischemia in patients at high risk for cerebral ischemia, for the assessment of level of consciousness in sedated or comatose patients, and for prognostication in patients after cardiac arrest.[92,93]

Data in support of these recommendations are robust. NCSs occur in up to 23% of children supported with extracorporeal membrane oxygenation (ECMO)[94] and 8% of neonates after cardiac surgery with cardiopulmonary bypass.[86] NCSs occur in approximately one-third of children with structural brain injuries, prior in-hospital convulsive seizures, or interictal EEG abnormalities.[95] In children with acute

encephalopathy, NCSs occurred in 36% to 46%.[90,96] The increasing use of cEEG in pediatric neurotrauma has identified the burden of NCS after TBI. In a prospective study of 87 children with mild to severe TBI, 43% had early post-traumatic seizures (PTS),[97] among which 16% were electrographic only.[97]

For ICU neurology, the EEG cannot be used to determine the etiology of abnormal patterns, discharges, or seizures. Seizures may be the presenting symptom of new ischemic (venous or arterial) or hemorrhagic injury in the critically ill patient. In the PICU, the detection of electrographic or clinical seizures should prompt investigation of common causes such as metabolic derangement, drug reaction, vascular injury, or infection. Often, a change in EEG pattern (loss of complexity, slowing, new epileptiform discharges) in the absence of seizures may also reflect new neurologic insult. The import of these changes can only be interpreted in the context of each patient's risk factors for neurologic injury. Importantly, routine EEG recording fails to detect NCS in approximately 50% of critically ill patients whose NCSs were detected with cEEG monitoring.[98,99] In patients in which NCSs are suspected, cEEG monitoring for at least 12 hours is required to detect an NCS.[8,99,100] An example of NCS epilepticus is shown in Fig. 62.3 in a patient with limbic encephalitis following cord blood transplant, whose only neurologic deficits were decreased sleep and loss of short-term memory.

FIG. 62.3 Bipolar EEG montage of an 11-year-old girl 4 weeks following umbilical cord transplant for acute myelocytic leukemia. Note the electrographic seizures at F4 and F8. This patient had limbic encephalitis due to reactivation of latent HHV6 infection. The only clinical manifestations of nonconvulsive seizures in this patient were loss of short-term memory and decreased sleep.

Before cEEG monitoring becomes a standard of care in selected critically ill children, studies are needed to show that treatment of NCS improves outcome. Here, too, evidence in support of treatment is accumulating. In a study of 259 patients with a variety of neurologic insults admitted to the PICU and cardiac ICU, these patients underwent cEEG monitoring.[90] Seizure burden was defined as the maximum percentage of any given hour occupied by electrographic seizures. The

maximum total seizure burden was much greater in patients with neurologic decline (15.7% per hour) than in patients without such alterations (1.8%). The odds of neurologic decline increased by 1.13 (95% CI = 1.05–1.21; p <0.0016) for every 1% increase in maximum hourly seizure burden. In a study of 300 children with an acute neurologic disorder (137 of whom were neurodevelopmentally normal) who underwent clinically indicated cEEG in the PICU, electrographic seizures and status epilepticus were associated with worse adaptive behavior after discharge than that observed in the previously healthy children.[88] Collectively, these studies suggest that seizures in critically ill children are associated with neurologic decline and may be a therapeutic target.

Transcranial Doppler Measurement of Cerebral Blood Flow

TCD is a noninvasive test that uses ultrasonography to measure the cerebral blood flow velocity (CBFV) in the anterior and posterior circulation. Normal values are described for healthy neonatal, pediatric, and adult populations,[101,102] measured by TCD; CBFV is lower in sedated critically ill children compared to age-matched healthy children.[23]

TCD has been used in adult and pediatric TBI[103-105] neonatal hypoxic-ischemic encephalopathy (HIE),[105] sickle cell disease,[106] and stroke[107] to assess autoregulation, predict mortality, and provide a target for goal-directed therapy. Elevated TCD velocities during pediatric ECMO may occur prior to neurologic injury including intracranial hemorrhage, increased ICP, or ischemia.[108] Vasospasm as measured by TCDs is common in children with moderate and severe TBI.[16] In this study of 69 children, vasospasm (velocities were compared to age- and gender-matched reference values in healthy children) occurred in 21% of those with severe and 8.5% of those with moderate TBI. In children with DKA studied with serial TCDs, autoregulation was compromised in 17% of 32 cases up to 72 hours after the initiation of treatment with insulin.[109] The effect of vasospasm on outcome and the optimal treatment for this complication is not known.

Near Infrared Spectroscopy

Near infrared spectroscopy (NIRS) measures tissue oxygen saturation by determining the difference in intensity between transmitted and received light delivered at specific wavelengths.[110] Commercial cerebral NIRS products measure oxygenation by using light with wavelengths of between 700 and 1000 nm to measure the transparency of tissue to light. Because hemoglobin absorbs NIRS light depending on its oxygenation state, changes in hemoglobin oxygenation can be quantified using the modified Lambert-Beer law. In theory therefore, NIRS may serve as a noninvasive method for detecting cerebral or somatic hypoxia. In practice, the reliability of cerebral NIRS was questioned[111] in a study showing that in infants up to 190 days old, cerebral NIRS values were not reproducible. In adult human cadavers, the cerebral tissue oxygenation measured by NIRS in a third of these subjects was higher than the lowest value of normal controls.[112]

As is the case for many of the technologies reviewed here, the adoption of NIRS as a standard of care has been limited by the retrospective design of many of these

single-center studies and the lack of evidence to show that targeting specific NIRS values improves organ function or outcome.[113] Despite this observation, results from studies in children with corrected congenital heart disease suggest that NIRS can detect perioperative cerebral hypoxia and that this reduction is associated with an increased risk for compromise of neurodevelopmental outcome.[114] In a study of postoperative congenital heart disease patients, cerebral and flank regional oxygen saturation were correlated with central venous oxygen saturation in both cyanotic or acyanotic patients and single- or two-ventricle physiology.[115] Change in $PaCO_2$ was associated with a change in cerebral but not flank regional oxygen saturation, suggesting that cerebral NIRS is detecting changes in cerebral oxygenation. A reduction in cerebral oxygen uptake during deep hypothermic cardiac arrest may not be associated with white matter injury, however.[116] NIRS may emerge an effective tool for mitigating perioperative neurologic injury in children with congenital heart disease.[117]

The validity of NIRS in other neurologic insults in children is also not established. A higher regional oxygen saturation may be associated with a greater chance of achieving a return of spontaneous circulation in adults with in-hospital or out-of-hospital cardiac arrest,[118] but such data in children are lacking. In a single-center observational study of infants with cerebral circulatory arrest, cerebral NIRS was significantly reduced in the patients with arrest compared to those with preserved cerebral perfusion.[119] However, the specificity of this difference was low.[118] In a pilot study of 28 children, NIRS was used in combination with head CT to detect the presence of intracerebral hemorrhage (ICH). NIRS (using a difference in optical density of >0.2 between hemispheres or scalp locations) correctly identified all 12 ICH cases.[120] An exciting development in the use of NIRS involves the autocorrelation of cerebral NIRS and mean arterial pressure as a noninvasive measurement of cerebral blood flow autoregulation.[121] A feasibility study of 36 children used autocorrelation of cerebral NIRS and mean arterial pressure (MAP) to identify the optimal MAP for preservation of cerebrovascular reactivity after cardiac arrest.[122] The cumulative evidence suggests that when monitoring for neurologic complications in both postcardiac surgery patients[123,124] and other acute neurologic insults in children, NIRS may contribute to ICU management.

Brain Tissue Oxygen Monitoring

The Neurotrend system, using a colorimetric method with optical fluorescence, measures three variables: O_2, pH, and CO_2; however, it is rarely used in clinical practice in the United States. The Licox system (Integra Neurosciences; Plainsboro, New Jersey) uses a Clark-type electrode and measures both $PbtO_2$ and temperature. The indications for placing the $PbtO_2$ monitor are the same as those for patients requiring ICP monitoring following TBI. Typically, the probe is placed in the white matter of the brain, because it is more metabolically stable than the gray matter. If the region of injury is to be monitored, the catheter is placed adjacent to, but not in, the region of contusion or clot, the insult, or in the ischemic penumbra. A retrospective analysis of 150 evaluable patients with severe TBI found that brain hypoxia ($PbtO_2$ <10 mm Hg) was associated with worse outcome and mortality.[125] There is debate as to whether the $PbtO_2$ monitor is estimating oxygen extraction or

CBF.[126-128]

In children, experience with $PbtO_2$ monitoring is increasing, particularly with severe TBI.[20,129,130] In a single-center study of 46 children with severe TBI, the probe was placed in the uninjured frontal cortex.[82] The authors found some cases in which $PbtO_2$ was preserved in the goal range but outcome was poor. CPP was the only factor that was independently associated with a favorable outcome at 6 months. Other pediatric studies have also reported a complex interaction between $PbtO_2$ and other clinical parameters.[131,132] In each of these studies, the analyses were based on hourly values for $PbtO_2$ and daily averages for $PbtO_2$ as opposed to episodes of $PbtO_2$ below predefined thresholds,[129] making comparisons among these studies difficult. Small series at single centers have suggested that $PbtO_2$ monitoring may augment the detection of CNS metabolic crises in children with stroke[133] and DKA.[82]

Differences in the site for probe placement and the thresholds selected for treatment limit meaningful comparisons between these studies. Further, $PbtO_2$ values may reflect both the presence of ischemia and other factors such as PaO_2. Further, $PbtO_2$ measures local tissue conditions and would fail to detect hypoxic-ischemic insults in remote brain regions. The promise of this technology for pediatric neuromonitoring is considerable but a number of caveats remain. For example, the threshold (10–15 mm Hg) for poor outcome is based on mostly adult data, and the dose-dependence of an exposure to cerebral hypoxia and the disease specificity for insults other than TBI remain to be determined.

Optic Nerve Sheath Diameter Measurement

Most of the experience with this technology is also in adults.[134,135] When ICP increases due to expansion of the subarachnoid space, this causes distention of the membrane of the optic nerve sheath, which is contiguous with the dura, and the maximal point of distention can be measured by ultrasound. Transorbital sonographic measurement of the optic nerve sheath diameter (ONSD) has been proposed as a noninvasive means to detect increased ICP in children.[136] A study of 103 healthy volunteers of whom 13% were younger than 16 years found a median ONSD of 4.41 (range 4.24–4.83) mm.[137] Results of studies using ONSD to detect increased ICP in children are equivocal. There was no significant difference of ONSD between children who had ventriculoperitoneal shunt failure (4.5 ± 0.9 mm) and those who did not (5 ± 0.6).[138] Overall, the pediatric data suggest that an ONSD above 4.75 mm may be abnormal, but data are lacking on the correlation with ICP measured by invasive methods and the timing of the increase and recovery of abnormal values related to the initial insult.

Tympanometry

Like ONSD measurement, tympanometry has been proposed as a noninvasive measure of ICP, and it has been subject to the same critiques of lack of accuracy and lack of availability for continuous monitoring.[139] The largest studies have been carried out in Africa in children with acute, nontraumatic coma and excluded children with epilepsy, neurodevelopmental delay, and sickle cell disease.[140,141] Children were more likely to die if tympanometry was abnormal (adjusted odds

ratio: 17; 95% confidence interval: 1.9–152.4; $p = .01$). The majority of the cases (53%) were caused by cerebral malaria and the remainder caused by bacterial meningitis, sepsis, or had no identifiable cause (30%). This technology needs further evaluation in studies that incorporate physiologic monitoring and brain imaging to validate this measurement. Nevertheless, the ease of use and potential in resource-poor countries justify further evaluation.

Cerebral Microdialysis

Cerebral microdialysis uses the capillary technique to measure the concentration of key metabolites (glucose, pyruvate, lactate), excitotoxic amino acids (glutamate and aspartate), and membrane breakdown products (glycerol) in the brain parenchyma in order to detect the evolution of primary and the development of secondary injury.[142] The microdialysis catheter is a fine tube, placed via a burr hole, within a semipermeable dialysis membrane that permits diffusion of molecules from the extracellular space along the catheter and into a vial. This vial is then placed in the microdialysis analyzer. In general, the catheter is placed via the same burr hole as the $PbtO_2$ and ICP monitors into the normal brain or penumbra of the injured brain. The most common system is the CMA600 microdialysis analyzer (CMA Microdialysis, Stockholm, Sweden). As with $PbtO_2$ monitoring, results will vary depending on the placement of the probe in healthy tissue, tissue adjacent to the primary site of injury (penumbra), or in the injured tissue.[143] A number of adult studies have shown, in TBI and SAH cases, an association between metabolic stress (lactate : pyruvate ratio >40) and poor outcome.[18] In a retrospective analysis of 20 adult patients with severe brain injury, tight systemic glucose control was associated with reduced cerebral glucose and with corresponding evidence (increased lactate/pyruvate ratio) of compromised brain metabolism.[144]

Data from adult studies have supported the use of cerebral microdialysis, primarily for the management of TBI and SAH, and have converged on specific values for each component of brain chemistry. Glucose, lactate, and the lactate/pyruvate ratio appear more useful than glycerol and glutamate. The 2004 consensus statement[143] on its use in neurocritical care was updated in 2015.[145] This expert opinion contains no recommendations about its use in children, and there are no recently published data to assess its risks and utility in the practice of pediatric neurocritical care.

Integrating Neurologic Monitoring Data

The growth in tools for invasive and noninvasive neuromonitoring in the ICU forces the issue of how to collect, integrate, and interpret these data.[146,147] It is clear that the use of physiologic thresholds to define good or bad values is oversimplified for pediatric neurocritical care in particular, based on limited data with no well-established age-dependent parameters.[148] This approach tends to interpret one variable in isolation from others and relies on the skill and experience of the clinician interpreting the data. Further, the volume of data generated on a minute-to-minute basis in the PICU places demands on the network used for storage of these data. The goal of plug-and-play mode for all devices (monitors, infusion pumps, ventilators)

that generate potentially clinically important data has not yet been achieved in the PICU. Indeed, these devices typically do not have a common source for recording time, rendering the interpretation of the timing of treatment, changes in ventilator parameters, laboratory results, or physiology open to question even if the obstacles to acquiring these data have been overcome. One approach may be to limit the acquisition of data only to those variables best validated for outcomes in TBI. This approach will likely miss unanticipated relationships, which may emerge only using an unbiased non–hypothesis-driven analysis of multiple variables. An example of this approach from a retrospective analysis of PICU data is shown in Fig. 62.4. Using a cluster analysis of all patients older than 1 year who required mechanical ventilation, the differences between survivors and nonsurvivors can easily be seen. This analysis incorporated thousands of variables ranging from census tract data to laboratory results and ventilator settings, and it demonstrates the potential of the application of these tools to the array of data generated in the PICU. Therefore to make use of the data generated by neuromonitoring, to interpret these data in relation to other physiologic and laboratory variables, and to develop new methods of analyses beyond thresholds and values at single time points rather than trends over time, it will be necessary to establish real-time data collection from all devices attached to the PICU patient, link these data (including waveforms) to laboratory and socioeconomic data, direct the flow of this information to new analysis tools, validate the data returning to the bedside, and iteratively develop and test predictive tools for the recognition of new or evolving cerebral injury. Substantial progress has been made in this area in adult neurocritical care[149,150] and in the development of automated algorithms for the detection of septic shock.[151] Thus progress in the application of neuromonitoring for the management of children with brain injury is fundamentally linked to the development of improved (better integrated, higher granularity) data collection and tools for bedside analysis using the emerging methods of bioinformatics.

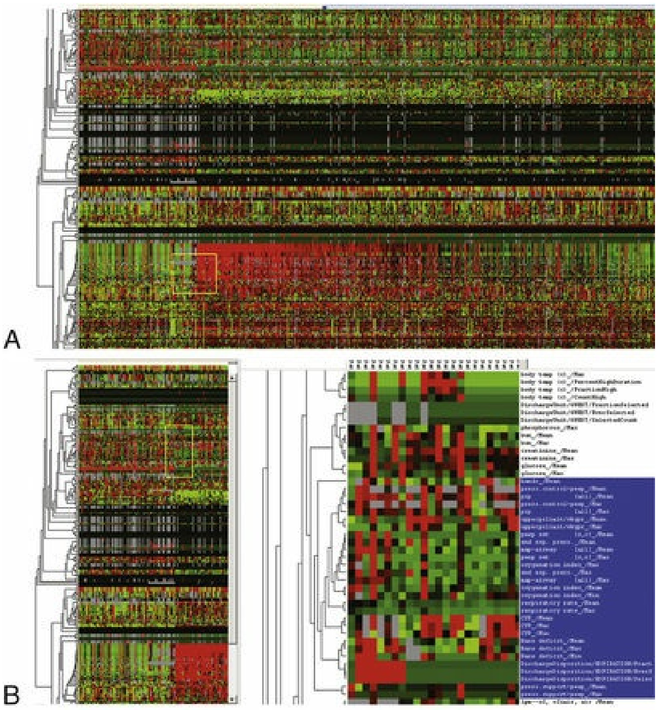

FIG. 62.4 (A) Master view of heat map analysis of all PICU patients over a 5-year period, older than 1 year, who required mechanical ventilation. The differences between survivors *(left)* and nonsurvivors *(right)* can easily be seen. This analysis incorporated thousands of variables ranging from census tract data to laboratory results and ventilator settings. (B) View of a selected cluster of variables highlighting those associated with differences in outcome after ventilation. This approach is proof of the principle of the potential of data mining in the ICU to discover novel relationships and generate hypotheses.

CHAPTER 63

Neuroimaging

Gisele E. Ishak, Dennis W.W. Shaw

PEARLS

- Multiple imaging modalities are available for evaluation of the brain, head, neck, and spine of the critically ill child. The most appropriate modality depends on consideration of patient pretest probability for the clinically suspected diagnosis, the modality sensitivity, and the patient's age and condition.
- When ordering radiographic studies, particularly computed tomography scans, the physician should keep the radiation burden in mind, especially for infants. When ordering magnetic resonance imaging for young children, one must keep in mind the risk related to sedation and general anesthesia.
- The ever-increasing complexity of imaging modalities and medical problems in the intensive care unit warrants liberal consultation with radiology colleagues to yield an appropriately tailored imaging protocol and a more relevant interpretation.
- In the pediatric population and especially in critically ill patients, noninvasive imaging modalities that are likely to answer the clinical question should carefully be considered as an alternative to a catheter angiogram, which though minimally invasive has a small but nonzero risk of procedure-related complications.

Imaging Modality Overview

Multiple imaging modalities are available to investigate the neurologic status of children in the intensive care unit (ICU). Selection of the most appropriate examination requires weighing factors of modality sensitivity against the suspected pathology, having a degree of suspicion for a particular pathology, and considering the practicalities afforded by the complexity of the examination and the child's condition. This chapter reviews available imaging modalities and the disease processes most likely to be subject to neuroimaging evaluation.

Ultrasound (see also Chapter 20)

Standard cranial ultrasound has been a mainstay in the neonatal ICU. Ultrasound

generates grayscale digital images from components of an ultrasound beam reflected off tissue interfaces with no ionizing radiation and with the added advantage that bedside imaging can be performed. However, cranial ultrasound has a restricted window through which to visualize the brain, primarily through an open anterior fontanelle, and therefore it is limited for the most part to the first few months of life. Ultrasound is sensitive to some intracranial pathology, including the detection of germinal matrix hemorrhage, evaluation of ventricular size, and evaluation of severe white matter lesions in premature infants, including cystic periventricular leukomalacia (PVL). It is less sensitive for pathologies such as mild to moderate parenchymal ischemic changes, subarachnoid and punctate parenchymal hemorrhage, dural venous sinus thrombosis, and subtle cerebral malformations. Extraaxial collections, especially those along the lateral cerebral convexities, also can be difficult to appreciate on ultrasound performed through a midline fontanelle.

Color Doppler with the standard ultrasound machine uses the shift in frequency associated with reflection of the sound beam off a moving interface (the "Doppler shift" phenomenon) to detect motion in the image field, most commonly from blood in vessels. Those pixels with movement are assigned a color to distinguish them from pixels without movement. The color assigned (most often red and blue) is different depending on whether movement is away from or toward the transducer, and the color assigned is arbitrary so that arteries and veins are not necessarily red and blue, respectively. Color Doppler allows for some investigation of the cerebral circulation, primarily through the open fontanelle. Transcranial Doppler (TCD) uses the same Doppler shift to produce waveforms that give information about flow velocity and direction. An advantage of TCD is that it can be performed through the thinner portions of the skull, primarily the temporal squamosa, in older children and adults (Fig. 63.1). TCD has been used in the evaluation of cerebral perfusion in patients with sickle cell disease[1] and vasospasm secondary to subarachnoid hemorrhage (SAH).[2] TCD is generally sensitive to vessel stenosis greater than 50% in the central cerebral circulation, with the highest sensitivity and specificity being in the middle cerebral artery (MCA).[3,4]

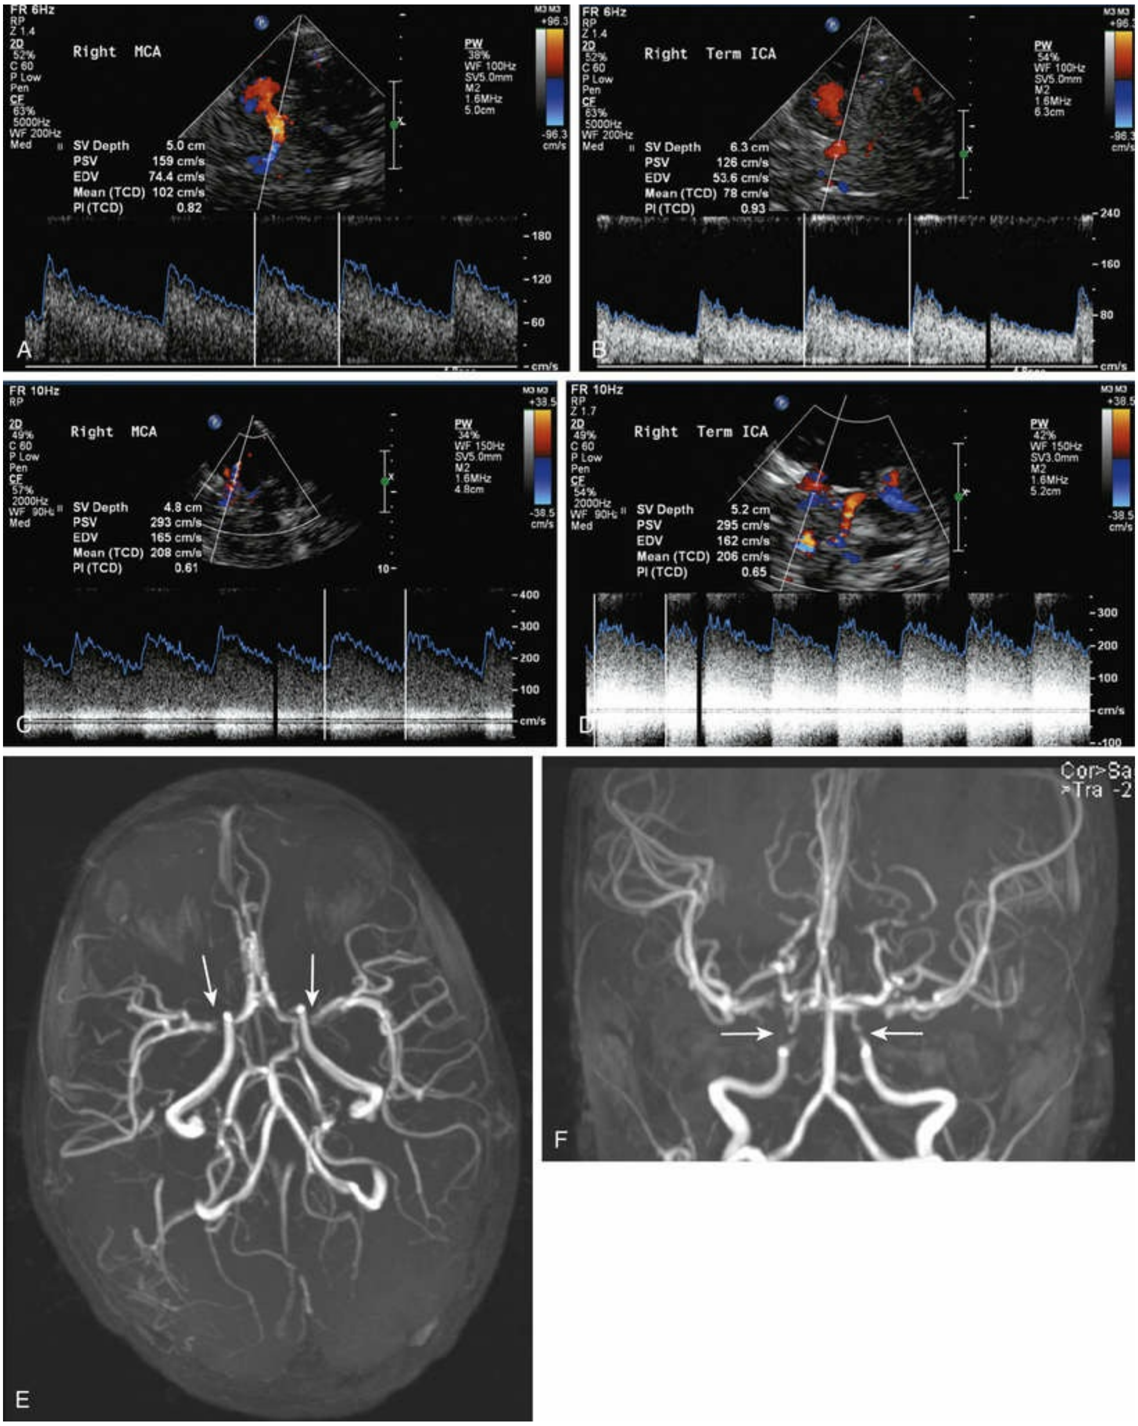

FIG. 63.1 Transcranial Doppler ultrasound images. Color and spectral Doppler waveforms from (A) normal right MCA and (B) right terminal internal carotid artery (ICA). Abnormal right middle cerebral (C) and terminal internal carotid (D) waveforms in another patient with sickle cell disease and prior history of stroke. MR angiographic images (E and F) of this patient with abnormal Transcranial Doppler demonstrate narrowed proximal MCAs and terminal ICA.

Computerized Tomography

Computerized tomographic (CT) scanning has higher sensitivity compared with

ultrasound for many intracranial pathologies, including most neurosurgical emergencies, and is not limited by closing and closed fontanelles. Imaging on modern scanners with multiarray detectors can be performed rapidly. CT, however, requires transporting the patient from the ICU (although some portable units are available) and uses ionizing radiation (x-rays) to produce digital computer-reconstructed images based on differences in tissue density (which affects x-ray attenuation). The choice of radiation parameters, slice thickness, postprocessing, and image viewing (window width and level) must be tailored to the particular clinical question to optimize the images. Newer scanners employing postprocessing algorithms utilizing iterative reconstruction harnessing greater computational power have allowed for decrease in the radiation dose required for any particular degree of image quality. Bone and other calcifications have the highest density, and in decreasing density are (nonadipose) soft tissue (such as the brain), water (eg, cerebrospinal fluid [CSF]), fat, and then air. The difference in density between bone and brain is great, whereas the difference between brain and fat is less. The density difference between gray and white matter is much smaller but is sufficient to be appreciated with the appropriate window and level. Generally, as edema develops in nonfatty tissue, there is a decrease in density. Acute blood (approximately between 12 and 72 hours old) is of higher density than brain, and CT is sensitive in the detection of acute (generally less than 1 week to 10 days old) parenchymal and SAH. CT is also useful in the evaluation of ventricular size, extraaxial collections, and to rule out cerebral herniation in the acute setting, as seen with space-occupying mass and diffuse cerebral edema.

Iodinated intravenous (IV) contrast can be used with CT to evaluate the integrity of the blood-brain barrier (BBB) and differences in tissue perfusion. With injection of IV contrast, vessels demonstrate a transient increase in density, with a variable rate of contrast leak into the tissues, depending on the local pathophysiology. The rate of equilibration of contrast concentration between vessels and parenchyma is much slower in the brain because of the intact BBB. Contrast then is especially useful in the brain, where disruption of the normal BBB can reveal underlying pathology. This increased density from contrast material is also used to image arteries and venous structures with CT angiography (CTA) and CT venography (CTV), respectively. With the appropriate software, postprocessing of the data can produce three-dimensional (3D) images of the vessels.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) utilizes a high-field-strength magnet in combination with radiofrequency pulses to produce images based on the nuclear resonance of hydrogen protons in tissue, primarily in water and fat. MRI provides the most sensitive measure of most (but not all) central nervous system (CNS) pathologies, and unlike CT, imaging can be acquired in any plane (although state-of-the-art multidetector CT scanners can acquire volumetric data that can be reformatted in any plane). Imaging, however, requires patient transport to the scanner; increased examination complexity and potential safety concerns are primarily related to the high-field-strength magnet (typically 1.5 or 3.0 Tesla) and generally longer imaging sequences (1 to 10 minutes). MRI provides the greatest tissue characterization, facilitated by several sequences obtained in a complete study.

MRI is particularly useful in the evaluation of the posterior fossa (brain stem and cerebellum) and spinal cord, where "beam-hardening" due to bone results in considerable artifact on CT, although this problem has become less of an issue with modern multidetector CT scanners.

Safety associated with MR scanning is an important issue. MRI-compatible monitoring and life support systems must be used. Patients need to be screened for any internal hardware or implants that would preclude scanning, such as MRI-incompatible aneurysm clips. Electronic devices such as pacemakers are rendered dysfunctional by the changing magnetic field occurring during MRI, and hence patients with such devices generally should not undergo MRI, though some exceptions are being developed. Other devices including extracorporeal membrane oxygenation (ECMO) lines, cochlear implants, and vagus nerve stimulators are also problematic. Many programmable shunts can be scanned but require reprogramming immediately afterward (further details are available at http://www.mrisafety.com). Injuries and deaths have been reported because of the failure to recognize these dangers. Most MRI sequences require imaging times in the range of minutes and are susceptible to motion degradation. Though newer sequences have increased tolerance for (minor) motion, for patients who are unable to cooperate, deep sedation or anesthesia is often required. "Fast and feed" approaches taking advantage of postprandial somnolence are often used successfully in young infants, thereby avoiding sedation. It also is important to screen the renal function of patients who might get an MRI because gadolinium-based contrast may need to be used. Gadolinium has been implicated in the development of nephrogenic systemic fibrosis in some patients with compromised renal function, which is not uncommon in the ICU setting.[5]

MRI exploits nuclear characteristics of hydrogen protons principally in tissue water, referred to as the T1 (longitudinal relaxation) and T2 (spin-spin relaxation) of the tissue. An imaging sequence includes both T1 and T2 components to create an image; however, an individual sequence can be formulated to be predominately one or the other—that is, T1 weighted or T2 weighted (often referred to as simply T1 or T2 sequences). Because most pathobiology results in some disturbance of water, these imaging parameters turn out to be sensitive to many pathologies. On T1-weighted images, water—such as CSF in the ventricles or vitreous in the globes—is dark. This water is bright on T2-weighted images. One point to be aware of is that for the most part the signal intensity of any tissue being imaged on MRI is relative (unlike the absolute density measure in CT). Hence the detection of pathology is dependent on visualizing differences in intensity of one tissue relative to another.

Fluid-attenuated inversion recovery (FLAIR) is a variation of T2-weighted imaging where the CSF is specifically rendered dark or suppressed so as to enhance visibility of hyperintense pathology in parenchyma, especially adjacent to normal CSF spaces. Fat is hyperintense on T1-weighted sequences and is also fairly bright on fast T2-weighted sequences, which is possible with most modern-day scanners. In some situations it is advantageous to suppress the brightness of fat, which can be specifically done at the cost of increased scan time. Gradient-recalled echo (GRE) and susceptibility-weighted (SWI) MRI sequences are often utilized for detection of hemorrhage, although these sequences generally also result in more artifacts. The appearance of acute blood on CT is fairly straightforward, appearing hyperdense initially (because of the extraction of serum), becoming isodense by about a week,

and appearing hypodense thereafter. The appearance of blood on MRI is much more complex, and although generally it is detectable for a much longer period of time, it can be difficult to appreciate hyperacutely (approximately less than 12 hours old) with MRI, especially with SAH. Overall, the detection of calcium and hyperacute blood can be difficult by standard MRI, and CT is often better in this regard, though newer gradient sequences, SWI in particular, are sensitive. IV contrast is also used in MRI, with similar application with CT. In this case the contrast is a gadolinium chelate that shortens the T1 relaxation time of nearby water. The result is that the water near gadolinium is hyperintense on T1-weighted images. This effect can be used to detect BBB disruption, which is seen in various pathologies including ischemia, inflammation/infection, and status epilepticus. Malignant and some benign brain tumors also demonstrate enhanced capillary permeability with enhancement following contrast. MRI with gadolinium is about an order of magnitude more sensitive than CT using iodinated contrast in detecting BBB disruption. Some areas of the brain lack the BBB, including the choroid plexus, pituitary stalk, the median eminence, and the pineal gland, and thus they enhance normally.

Diffusion-weighted imaging (DWI) has assumed an invaluable role, particularly in the intensive care setting. This sequence is now integrated into most brain MRI examinations and is particularly sensitive to areas where brain parenchyma has sustained acute cytotoxic injury, most commonly but not limited to ischemia. DWI is sensitive to the motion of water at the molecular level.[6] Detecting this molecular level motion requires strong fast gradients that have become standard on modern-day MRI scanners to allow sufficiently rapid scanning to effectively "freeze" the gross tissue motion that normally swamps this molecular level motion. Different cerebral pathologies produce different types of edema (eg, cytotoxic, vasogenic, and interstitial) (see also Chapter 66). Evaluation of the molecular (Brownian) motion of water turns out to be a sensitive measure of some pathologic states, the most significant application currently being cytotoxic edema associated with the detection of ischemia.[7] Cytotoxic edema causes "restriction" of water diffusion with a decrease in the apparent diffusion coefficient (ADC). This is seen as hypointensity on the calculated ADC map image but is more easily appreciated as hyperintensity on the DWI "trace" image. In contrast to cytotoxic edema, vasogenic and interstitial edema result in "increased" water diffusion and therefore an increase in the ADC. Care must be taken in interpreting the DWI trace images because they have some T2 weighting, and "T2 shine-through" can result in a focus of increased signal on DWI trace images that does not represent true restricted diffusion. Review of the calculated ADC map images should show a corresponding darkening in a focus of cytotoxic edema to confirm restricted diffusion. Also, the hyperintensity on DWI trace images may "pseudo-normalize" for a period of time several days following the ictus because of the development of associated vasogenic edema. Restricted diffusion due to infarct will generally resolve over the course of 1 to 3 weeks and allows a new infarct to be distinguished from older lesions. It also should be noted that restricted diffusion is not limited to ischemia and can be seen in other acute cerebral pathologies, primarily myelin vacuolization as can be seen in acute demyelination, infection, and highly cellular brain tumors.

Advanced Magnetic Resonance Imaging Techniques

Newer techniques in MRI such as MR perfusion, MR spectroscopy (MRS), and

diffusion tensor imaging are providing new information that is being increasingly utilized in the management of critically ill patients.

Perfusion MR is used in the evaluation of cerebral perfusion. The most widely available techniques use rapid scanning associated with a bolus of IV gadolinium contrast to measure first-pass changes in signal intensity. These techniques give a relative measure of perfusion but not quantitative flow. This relative measure can be used to detect diminished cerebral blood flow in one area compared with another. Newer noncontrast MRI techniques such as arterial spin labeling generally have lower signal-to-noise ratio (sensitivity) but are improving and potentially quantifiable. There is some early experience with arterial spin labeling in pediatric stroke cases resulting from sickle cell disease.[8,9]

Conventional MRI is based on the signal intensities derived from the hydrogen bound to oxygen in water and, to a lesser extent, the hydrogen bound to carbon in fat. With the appropriate software, MR can be used as a "probe" for hydrogen bonded to other molecules (termed *MR spectroscopy*). The sensitivity is sufficient to detect metabolite molecules in the millimolar range, although at a much lower resolution than that used to detect water for imaging. The nonwater molecules are most commonly reported as ratios of signal peaks that correspond to one of several molecules. In the brain the most common metabolite peaks detected are N-acetyl aspartate, creatine, choline, and in some physiologic states, lactate. The MRS signal is either obtained from a single voxel (usually several mL in volume; voxel is the "volume element" of the image = pixel × depth) or multiple voxels (as small as 1 to 2 mL in volume). Multivoxel MRS can be used to make low-resolution images using a technique termed *chemical shift imaging* for some of the more prevalent metabolite peaks. The utility of MRS is still in evolution, and newer variants of MRS are constantly being evaluated. Detection of lactate to evaluate newborn ischemia, some metabolic diseases, and brain tumors is one of the ongoing applications and areas of research. MRS also has a role in imaging children with mitochondrial disorders[10] and has been applied in creatine deficiency syndromes as two examples of clinical applications.

Magnetic Resonance Angiography

Fluid motion within tissues can be used by MRI to image flow in vessels and CSF. This imaging can be accomplished with and without contrast, although contrast techniques are generally more sensitive for vascular flow, with some newer contrast angiography sequences also providing temporal/flow information. The MR angiogram can be tailored for artery (MRA) or vein (MRV) visualization, primarily based on flow direction, and is usually most effective if the area of interest can be narrowed—for example, the circle of Willis—although newer techniques have greatly increased the area that can be covered in one scan. The maximum resolution of MRA of slightly under 1 mm is generally less than CTA, where the maximum resolution can be under 0.25 mm.[11] In addition to the source images (the thin angiographic sections obtained during the scan), various reconstructed images can be obtained, including 3D rotational reformations derived from maximum intensity projection reconstructions (Figs. 63.2 and 63.3) and surface renderings, which also can be viewed from multiple projections. Time-resolved MRA techniques (such as TWIST), which utilized the first pass of gadolinium-administered IV, have begun to make inroads in providing temporal information on vascular lesions, previously

only available with catheter angiograms, though the latter remain the gold standard. Many clinical cerebral arterial questions, however, are now answered with MRA, and MRV of the superficial and deep venous systems has largely replaced diagnostic catheter venograms.

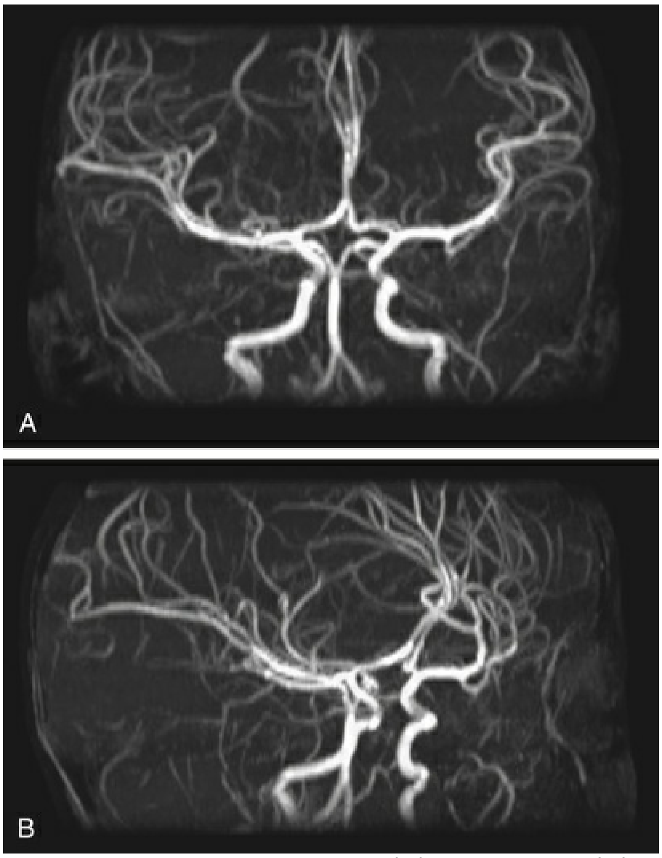

FIG. 63.2 Normal MRA scans. Frontal (A) and oblique (B) maximum intensity projection images from an MRA demonstrate normal anterior and posterior circulations.

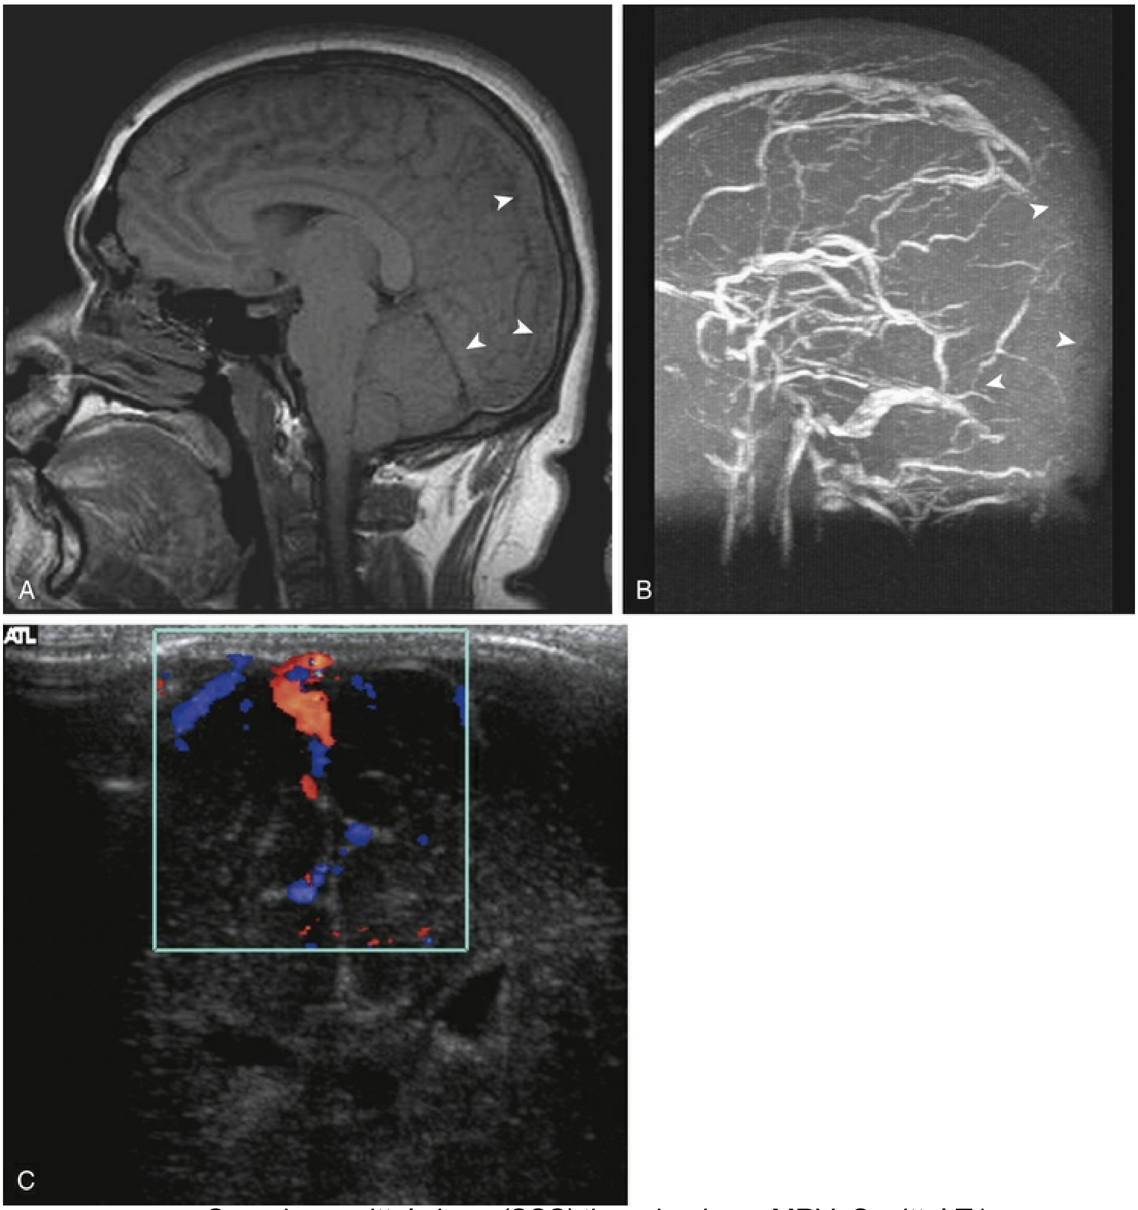

FIG. 63.3 Superior sagittal sinus *(SSS)* thrombosis on MRV. Sagittal T1 magnetic resonance imaging (A) shows intermediate signal intensity in sagittal and straight sinuses *(arrowheads)*. No flow is seen on MRV (B) in these vessels *(arrowheads)*, which is consistent with thrombosis. Color Doppler evaluation (C) of the SSS in another 6-month-old patient with suspected thrombosis demonstrated a patent SSS with normal draining cortical veins (see color inset).

Catheter Angiograms

Although significant inroads have been made in cerebral vascular evaluation with both CTA and MRA, when indicated, catheter angiography remains the gold standard for most CNS arterial imaging. Catheter angiography also provides temporal/flow data, such as appreciation of early venous drainage with arteriovenous malformations. Angiography is basically a rapid series of radiographs obtained during injection of iodinated contrast directly into the arteries or veins being imaged. Most angiography units produce digital images using digital

subtraction (hence the term *digital subtraction angiography*)—that is, images where the background "mask" has been subtracted, leaving an image primarily of the contrast-filled vessels. High-end modern-day units utilize biplane technology that permits acquisition of digital angiographic images from multiple projections using a single contrast injection. This technology also can be used to derive 3D rotational angiograms, images that can be further postprocessed to obtain volume-rendered and surface-shaded images. Catheter angiography requires transport to and patient support in the angiography suite. Vascular access for arterial studies is usually through the femoral artery and generally has a small but "nonzero" risk of vessel injury, including dissection and embolization. In very young patients, injury to the femoral artery is of greater concern, and although any acute risk to the limb is extremely uncommon, relative diminished leg growth in some cases has been reported. Risks of neurologic complication following cerebral angiography are small but do exist; the incidence of permanent defects in diagnostic angiograms using modern techniques is typically reported in the range of 0.5% to 0.07%.[12,13] Therapeutic endovascular procedures carry higher risks but generally are in lieu of riskier neurosurgical procedures or at times are the only or preferred avenue of treatment.

Myelography

Myelography involves radiographs or CT of the spine following opacification of the subarachnoid space by intrathecal injection of iodinated contrast, most commonly injected at the lumbar level. The myelogram has almost completely been replaced by MRI, especially in the pediatric population, because MRI can depict both extrathecal encroachment and intrathecal masses, as well as evaluate signal characteristics of the spinal cord itself and any intramedullary mass. High-resolution myelographic type contrast can be achieved using MRI with 3D constructive interference in steady state and volume T2 sequences to investigate pathologies where detailed anatomic information is needed, such as with spinal nerve root avulsion and cranial nerve pathologies.

Exceptions where imaging may revert to CT include the inability to obtain an MRI either because of local field disruption, most commonly from ferromagnetic spinal rods, or because of MRI incompatibility due to safety issues (eg, a pacemaker). CT provides better results than MRI in the evaluation of the bony spinal column, particularly in patients with trauma, whereas MRI is used in patients with trauma to evaluate soft tissues in the spinal column, primarily the spinal cord.

Nuclear Medicine

Most nuclear medicine studies involve injection of a very small amount of radioactively labeled substance (radiopharmaceutical tracer compound or radiotracer) and follow either the physiologic uptake and metabolism of the radiotracer or the movement of the radiotracer with a gamma camera.

Technetium pertechnetate and technetium-diethylenetriamine pentaacetic acid (Tc^{99} DTPA) are radiotracers used for radionuclide cerebral angiography to evaluate cerebral perfusion, and they can be used to support a clinical diagnosis of brain death. Single photon emission computed tomography imaging using technetium-

hexamethylpropyleneamine oxime (Tc[99] HMPAO) as the radiotracer is used to monitor for cerebral perfusion defects in patients with SAH who are at risk for vasospasm. With use of acetazolamide (Diamox), a carbonic anhydrase inhibitor, Tc[99] HMPAO single photon emission CT (SPECT) can be used to evaluate cerebral reserve in patients with stroke.

Ventriculoperitoneal (and ventriculoatrial and ventriculopleural) shunt function evaluation often includes a nuclear medicine shunt study. Flow in the shunt is assessed by injecting a small amount of radiotracer in the shunt reservoir and following the movement of the activity with a gamma camera.

Preterm and Term Neonate Imaging

In the premature infant, ultrasound remains the primary modality for detection and follow-up of germinal matrix hemorrhage and to detect intraventricular extension as well as hemorrhagic parenchymal venous infarction; in the neonate, it remains the primary modality to evaluate for hydrocephalus (Fig. 63.4). Furthermore, assessment can be made for white matter injury including periventricular leukomalacia, especially the cystic form, although MRI will be more sensitive for noncystic periventricular leukomalacia, and MRI in preemies performed at about the third week of life has been reported as predictive of outcome at term.[14] Routine screening cranial ultrasound has been recommended for all infants younger than 30 weeks' gestation between day 7 and day 14, optimally repeated at 36 to 40 weeks' gestation.[15] Moderate to large parenchymal and extra axial areas of bleeding also can be detected with ultrasound. As previously mentioned, smaller extra axial collections, especially laterally along the cerebral convexities, can be missed with ultrasound, as can small parenchymal hemorrhages.

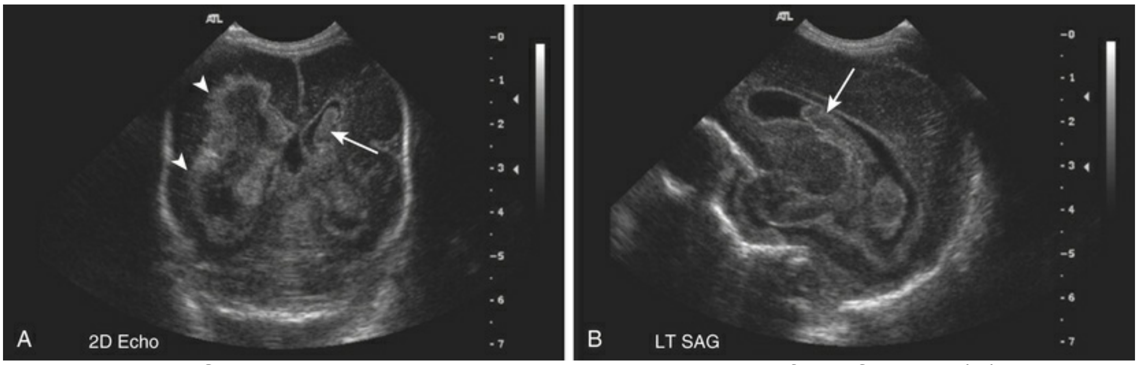

FIG. 63.4 Germinal matrix hemorrhage in a premature infant. Coronal (A) and left parasagittal (B) ultrasound images through the anterior fontanelle demonstrate dilated lateral ventricles with intraventricular extension of clot on the left *(arrows)* and periventricular hemorrhagic venous infarction on the right *(arrowheads)* consistent with a grade 3 hemorrhage on the left and grade 4 hemorrhage on the right (some radiologists would assign this hemorrhage an overall grade of 4).

As noted in Chapters 60 and 68, understanding of hypoxic-ischemic encephalopathy (HIE) in children is complicated by the developmental status of the child. The pattern of injury seen is determined by the characteristics of the insult and

the maturational state of the brain. Metabolic demands and regions of selective vulnerability evolve during development. Grayscale ultrasound, which is widely used for intracranial imaging in the neonate, is relatively insensitive to acute changes associated with HIE.[16] As edema develops, usually after several hours, increased echogenicity of brain parenchyma can be seen, but this measure is nonspecific, relative, and often is difficult to appreciate. Blood associated with a hemorrhagic infarct also will appear as increased echogenicity. As mass effect develops secondary to edema, ventricular and sulcal effacement can be seen. Later, vascular and perivascular mineralization can result in linear thalamic and basal ganglia echogenicities (lenticulostriate vasculopathy or mineralizing angiopathy).[17] Ultrasound Doppler evaluation of newborn ischemia has shown some utility. Brain perfusion can be investigated by determining the resistive index (RI). RI in the normal neonate (0.75 ± 0.1) is higher than that seen in the older infant before (0.65 ± 0.5) and after (0.55 ± 0.5) fontanelle closure.[16] An increase in the RI with a decrease in the peak systolic velocity and end-diastolic velocity in infants with HIE within the first 12 hours of life as measured in the anterior and middle cerebral arteries correlated with a poor prognosis at 1 year of life. A decrease in RI to less than 0.60 at 12 hours (anterior and middle cerebral arteries) and 24 hours (all insonated arteries, including basilar artery) after neonatal asphyxia, which is thought to be a result of the decreased vascular tone associated with loss of autoregulation, has been associated with a poorer outcome at 12 to 18 months of life.[18,19] Approximately half of patients with low RI scores have normal grayscale images. There is a host of other reasons for low RI scores, however, including cardiac disease, extracorporeal membrane oxygenation, ongoing hypoxemia, hypercapnia, and technical issues. It also should be noted that increased fontanelle pressure can increase the RI measure by 20%, hence there is considerable user dependence to this application. If hyperemia persists, and as HIE evolves, cytotoxic edema increases and leads to increased intracranial pressure and increased RI measurements. A high RI score on the first day of life with evidence of neonatal insult suggests an in utero injury. Although some centers have continued to pursue the use of ultrasound, MRI has supplanted much of this evaluation.

CT detection of acute ischemic injury also depends on edema resulting from the injury. Edema is seen as decreased attenuation and loss of gray-white differentiation, usually detected several hours postinsult.[20] Small or early infarcts can be missed with CT, and detection of ischemia in the newborn is made more difficult by the generally lower attenuation of the relatively “watery” unmyelinated newborn brain. For this reason, in some instances of neonatal ischemic injury, there may actually be an increase in the attenuation of this watery unmyelinated white matter because of an outpouring of serum proteins from damaged blood vessels. As brain swelling develops in the first few days, there can be a loss of CSF spaces seen as ventricular compression, sulcal effacement, and loss of perimesencephalic cisterns. Acute thrombotic stroke associated with arterial thrombosis can at times be appreciated acutely as a hyperdense artery, most commonly the middle cerebral artery on noncontrast CT. Acute hemorrhage, such as with hemorrhagic arterial (from reperfusion) or venous infarcts, will be hyperdense initially on CT, evolving to isodense over the first week.

Standard MR sequences exploiting T1 and T2 relaxation times also depend on the development of edema to appreciate acute ischemic injury, which results in

hyperintensity on T2-weighted and FLAIR images and hypointensity on T1-weighted images. This change typically takes at least several hours to develop, and although generally more sensitive than CT in adults, evaluation of the newborn is again made somewhat difficult by the lack of myelination. As a result, ischemia sometimes can be more conspicuous on CT than on T1- or T2-weighted MRI (Fig. 63.5). The FLAIR sequence has proved to be more sensitive than T1 and T2 to ischemic changes in older myelinated children and adults. DWI is more sensitive than T2 and FLAIR sequences and correlates well with at least short-term neurologic outcome in neonates and infants.[21] These sequences, as previously discussed, have been shown to be acutely sensitive to the cytotoxic edema associated with ischemia.[7] This cytotoxic edema results in diminished diffusion of water in the affected area. DWI in experimental models can detect ischemia in minutes after onset as a region of restricted diffusion.[22,23] These sequences have now become widely implemented in adult and pediatric neuroimaging, where differentiation of acute ischemic stroke from other neurologic disorders permits appropriate and timely implementation of stroke therapies. The restricted diffusion associated with ischemia evolves over a 1- to 3-week period, at which time the diffusion image usually normalizes. If sufficient tissue destruction has occurred, the diffusion ultimately will increase because of the greater amount of free water following necrosis. This change in diffusion is also useful in distinguishing a new stroke (which will show decreased diffusion) from an older lesion (which will have increased diffusion), whereas both lesions may be of similar signal intensity on standard T1 and T2 imaging (Fig. 63.6).

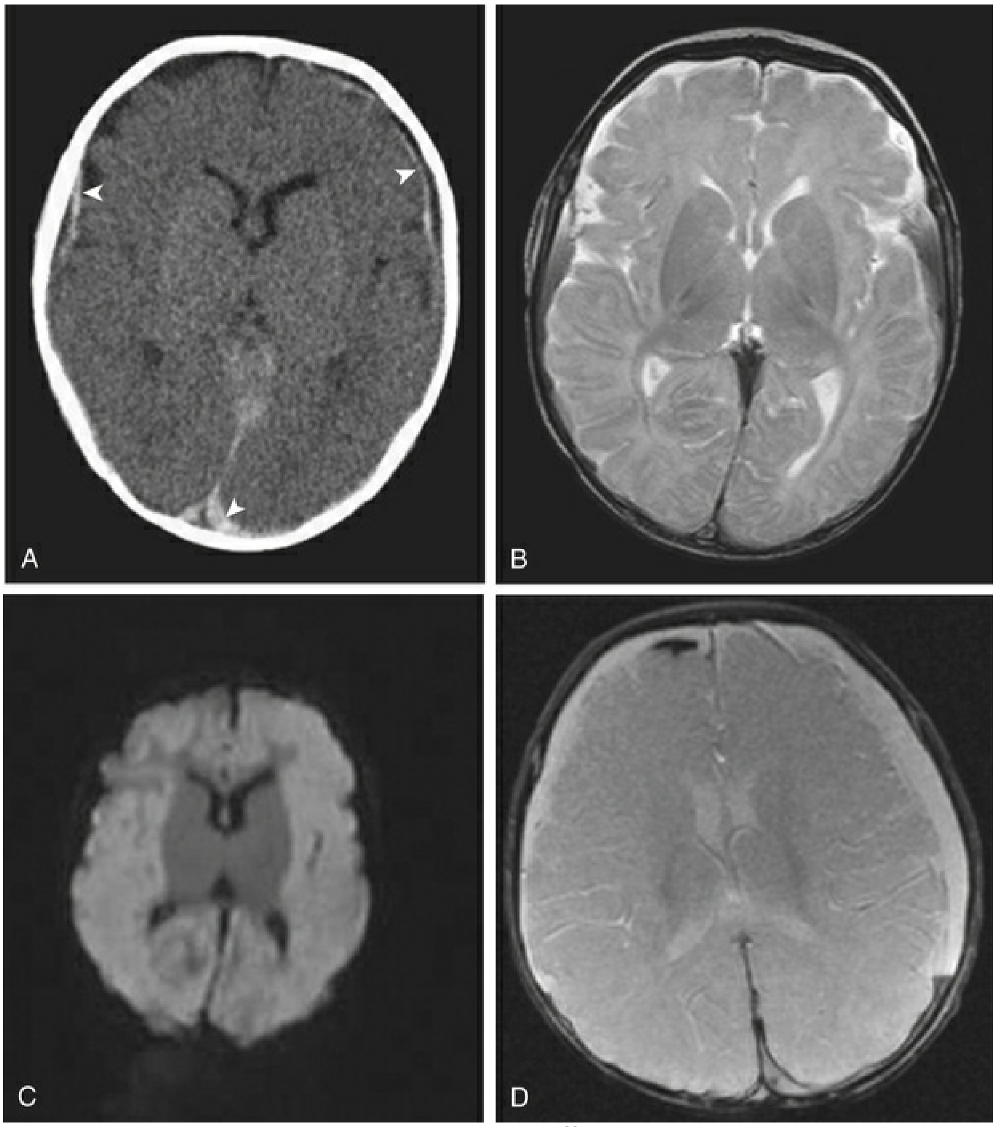

FIG. 63.5 Nonaccidental trauma with diffuse cerebral ischemia. Axial noncontrast CT (A), axial T2-weighted (B), and diffusion-weighted MRI (C). (A) CT shows a thin layer of acute subdural blood *(arrowheads)* and diffuse loss of gray-white demarcation in the cerebral hemispheres. (B) Although the T2 image appears remarkably normal with appropriate lack of myelination in this 3-month-old child, the relative brightness of the cerebral hemispheres compared with the central gray on diffusion-weighted images (C) is consistent with a diffuse ischemic insult. (D) Gradient-recalled echo MRI in another 4-month-old with nonaccidental trauma demonstrates dark, low signal areas in the right frontal subdural space and left posterior parafalcine regions, consistent with subdural hematomas.

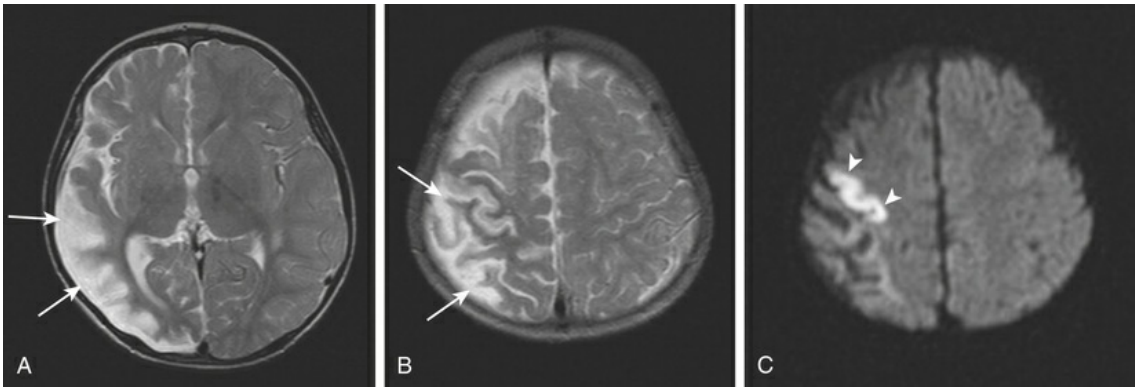

FIG. 63.6 Remote and acute infarcts. Axial T2-weighted MRI (A and B) shows cerebral volume loss with encephalomalacia and gliosis *(arrows)* associated with an old stroke in this child with new onset of progressive left-sided weakness. Diffusion-weighted MRI (C) reveals a new area of infarct *(arrowheads)* at the edge of the remote abnormality.

Timelines for relative T2 and diffusion changes have been shown to differ in neonates and infants versus older children and adults. Animal models have suggested that diffusion changes in neonates and infants with HIE do not necessarily precede T2 changes. This finding is presumably a result of age-dependent differences in brain water content and changes therein as a result of differences in vascular permeability in response to hypoxic-ischemic insult.[24,25] The initial diffusion abnormality may increase over the first day, and the extent of the diffusion abnormality can encompass both the core infarct as well as penumbra and hence potentially overestimate the ultimate infarct. This potential overestimation could be an indication for MR perfusion, which can separate the areas of core infarction and penumbra.[26] The identification of lactate on MRS is also evolving as a useful tool that may serve as a predictor for the severity of perinatal asphyxia, although considerable complexity is involved, which has limited application of this technology.[22,27]

As previously mentioned, the pattern of hypoxic-ischemic injury varies with the etiology of the insult, as well as the developmental state of the brain. Early in utero insults result in tissue resorption, without the ability to mount a gliotic response that is not seen until the third trimester. During early brain development, insults can result in congenital malformations. HIE or injury in the early to middle second trimester may result in polymicrogyria with or without associated schizencephaly. In the 24th to 25th week of gestation range, HIE can preferentially injure the deep gray matter nuclei in the setting of total asphyxia. PVL is the pattern of injury seen with prolonged partial hypoxia at 24 to 34 weeks. Typically with PVL on neonatal grayscale ultrasound, there may be increased echogenicity in the periventricular white matter, an appearance that is indistinguishable at this stage from edema or from parenchymal hemorrhage, which also may be seen. As PVL progresses, cystic change occurs that progresses to coalescent cavitation of the involved white matter, and collapse of these spaces results ultimately in the thinning and volume loss of the white matter, particularly in the posterior periventricular white matter. Although cranial ultrasound affords better resolution for the visualization of cystic change of early PVL in the premature neonate, MRI has overall greater sensitivity to white matter injury, especially in the more advanced stages of PVL, and demonstrates an undulating ventricular margin with associated periventricular T2/FLAIR signal abnormality with or without a paucity of white matter. However, it is not yet clear if

this increased sensitivity is of significant prognostic value. Ischemic insults to the term child demonstrate different patterns of injury, determined by the specifics of the insult and the vulnerability of various areas. Profound hypoxia in the term infant results in injury largely to areas that are most actively myelinating, in particular the perirolandic white matter and the associated corticospinal tracts and the white matter tracts associated with the occipital cortex, as well as other areas with high energy demands such as the putamina, thalami, hippocampi, and brain stem. In contrast, a watershed pattern of injury discussed in the next section develops with prolonged partial ischemia that is not sufficient to cause an infarct of the cerebrum, with shunting to the high-energy demand areas. Current recommendations for the encephalopathic term infant have included early CT to assess for intracranial hemorrhage, with consideration for MRI with DWI and GRE sequences later in the first postnatal week to assess the extent of injury.[15]

Stroke in the Older Infant/Child

Although the imaging picture may not be specific, a diagnosis of acute stroke usually can be made in combination with the clinical history (as discussed in Chapter 69).[28] The imaging pattern can be of help in determining an etiology. A watershed distribution is consistent with a low flow/hypotensive cause (Fig. 63.7). Specifically, changes of ischemic injury are seen at the boundary regions between the major cerebral distributions—that is, between anterior and middle cerebral territories and between middle and posterior cerebral arterial territories. Lesions involving multiple arterial distributions suggest a central thrombotic source, although other causes such as a vasculitis or demyelinating diseases also can have this multivessel or multifocal picture (Fig. 63.8). Classically, embolic lesions will tend to be seen at the gray-white junction and most commonly in the MCA distribution. Individual variability of boundary regions[29] and pathology-induced alteration in flow limit the definitiveness of arterial distribution categorization following vascular insult.

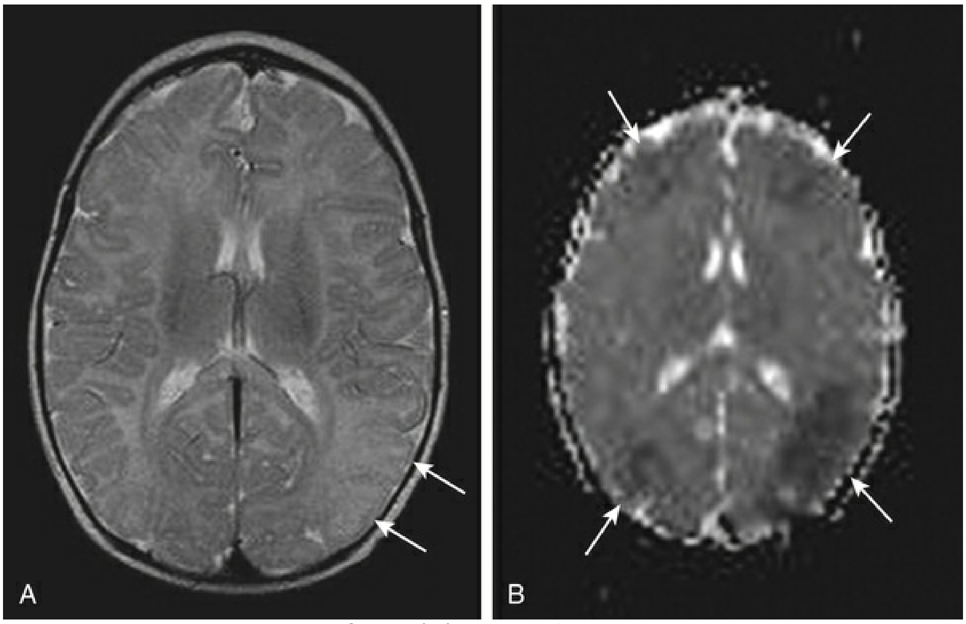

FIG. 63.7 Watershed infarct. (A) Axial T2-weighted MR image shows some loss of the gray-white interface on the left posteriorly *(arrows)*. (B) Diffusion-weighted image shows bilateral restricted diffusion consistent with ischemic injury in a watershed distribution *(arrows)*.

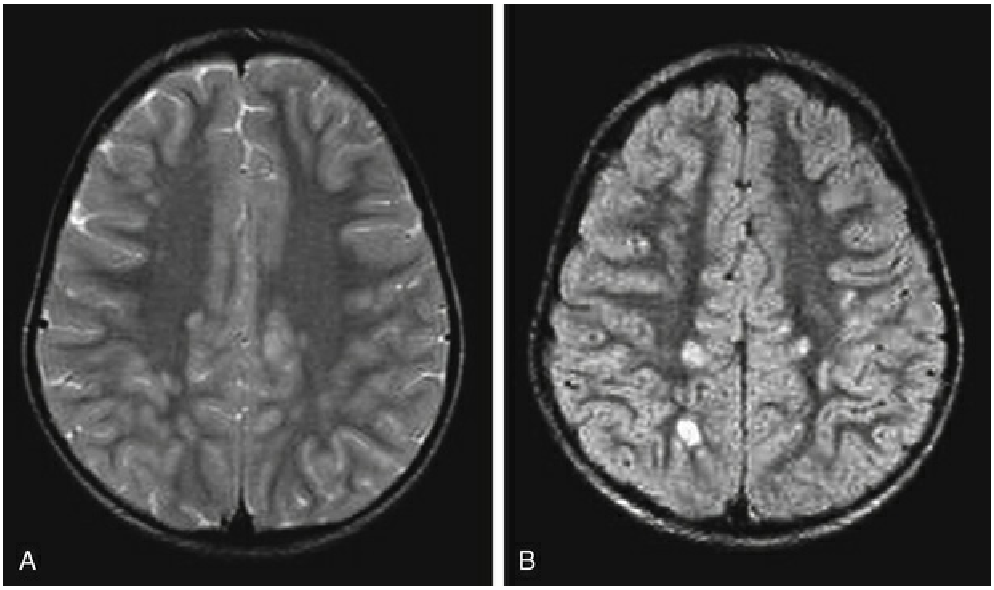

FIG. 63.8 ADEM. T2-weighted (A) and FLAIR (B) images show multiple foci of hyperintensity. In addition to ADEM, vasculitis and multiple emboli could have this imaging appearance.

As previously discussed, diffusion-weighted imaging also proves to be very useful in earlier imaging detection of cerebral infarcts (Fig. 63.9) and separating recent infarcts from a background of abnormality, such as prior infarcts (see Fig. 63.6). The area of restricted diffusion on DWI is generally thought to represent irreversible injury, especially when associated with T2/FLAIR signal abnormality, although there may be some cases in which the lesions are at least potentially reversible. In the

setting of acute stroke, perfusion MRI may have a contributory role in demonstrating the total region of brain at risk (penumbra) and predicting the ultimate extent of infarct.[26] The area of perfusion abnormality beyond that of diffusion abnormality is thought to represent the penumbra and to be at risk but potentially salvageable. The presence of hemorrhage with a stroke can represent hemorrhagic conversion of a "bland" stroke or an underlying vascular lesion. A large study found an incidence of hemorrhagic stroke of 1.4 per 100,000 person years in those younger than 20 years of age. An underlying aneurysm was found in 13%, including 57% of those with pure SAH, 2% of those with a pure parenchymal hemorrhage, and 5% of those with a mixed hemorrhage.[30]

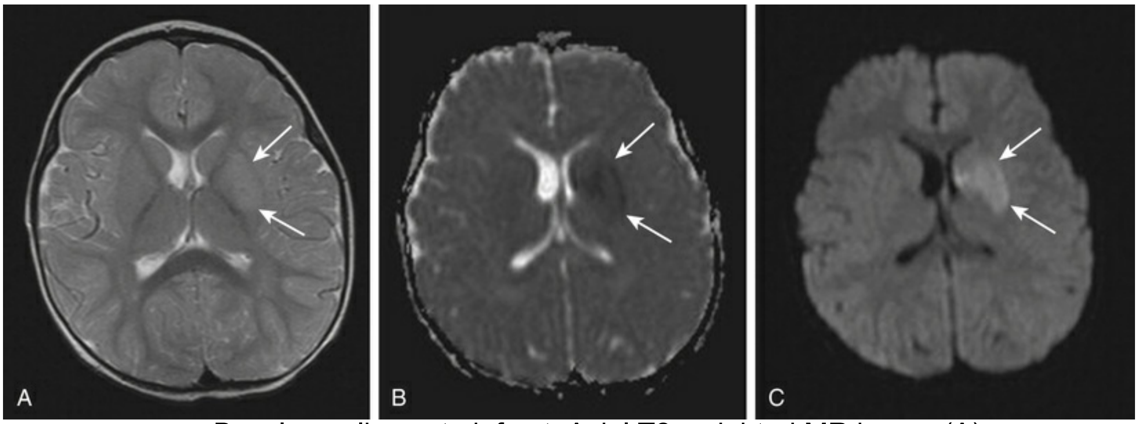

FIG. 63.9 Basal ganglia acute infarct. Axial T2-weighted MR image (A) shows subtle increased T2 signal in left basal ganglia *(arrows)*. More conspicuously shown on the apparent diffusion coefficient map (B) and diffusion-weighted images (C) is restricted diffusion *(arrows)* associated with an early infarct involving the left caudate and lentiform nuclei.

Posterior Reversible Encephalopathy Syndrome

Posterior reversible encephalopathy syndrome results from a loss of autoregulation in the older infant and child as seen in hypertensive encephalopathy, cytotoxic and immunosuppressive drug neurotoxicity, and thrombotic thrombocytopenia purpura. Typically posterior reversible encephalopathy syndrome preferentially involves a posterior and parasagittal distribution of the brain with T2 and FLAIR hyperintensities and also less frequently can involve the frontal lobes and brain stem.[31-33] Lesions often are relatively symmetric with confluent lesions centered in the subcortical white matter that rarely demonstrate patchy enhancement (Fig. 63.10). Frequently, because the underlying pathology causes only vasogenic edema, these lesions will not be restricted on DWI. However, ischemia can be triggered by a severe increase in blood pressure, resulting in superimposed cytotoxic edema and therefore diffusion-restricted lesions that usually result in infarctions, the severity of which often correlates with prognosis.

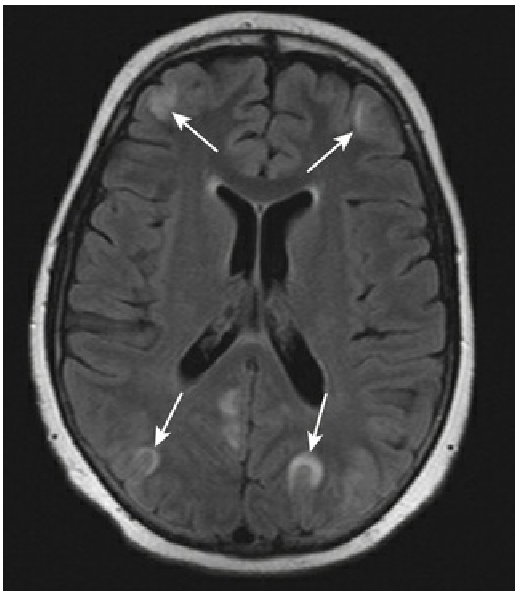

FIG. 63.10 Posterior reversible encephalopathy syndrome. Axial FLAIR MRI showing subcortical foci of hyperintensity *(arrows)* associated with cyclosporin toxicity. Note that abnormalities may have a variable distribution and are frequently, but not always, posterior in location.

Venous Infarct

The presence of blood in an area of cerebral infarct raises consideration for a venous stroke, although an arterial-induced stroke occasionally can have associated hemorrhage (reperfusion injury). A nonarterial distribution infarct also raises suspicion of a venous stroke. In the setting of suspected venous stroke, evaluation of the cerebral venous system should be undertaken. Ultrasound has limited utility in this setting, although evaluation of superior sagittal sinus flow can be undertaken in the young infant with an open fontanelle (see Fig. 63.3C). CT evidence of a venous clot can be detected as hyperdense venous sinuses acutely on noncontrast scans and as the "empty delta sign" (lower density in area of clot surrounded by enhancing blood) in the superior sagittal sinus on contrast-enhanced scans. This assessment can be problematic in the newborn in whom the normal low-density unmyelinated brain and typically higher hematocrit make the venous sinuses appear dense normally on CT. Classically, the venous phase of a catheter angiogram has been used to look for venous sinus thrombosis. Catheter evaluation of the venous sinuses, however, has been effectively replaced with MRV techniques. MRV uses flow-sensitive sequences that can delineate the major venous sinuses quite effectively (see Fig. 63.3A and B). A subacute clot in a venous sinus also can be evident on standard T1- and T2-weighted MRI as bright areas in the venous sinuses, although an acute clot can be more difficult to appreciate. On MRI, GRE sequences may demonstrate low signal, and T1 contrast-enhanced sequences may demonstrate areas of nonenhancement of thrombosed venous sinuses.

Etiologic workup of stroke in children includes a broad differential (see also Chapter 69). Although catheter angiogram remains the gold standard and is necessary occasionally, ruling out a vascular lesion has evolved, with greater use of MRA and CTA.

Arterial dissections can be diagnosed with MRI and MRA or with CTA. Visualization of methemoglobin in the false lumen with fat-saturated T1-weighted or proton density–weighted MRI sequences detects most dissections, although subtle lesions may still require catheter angiogram for diagnosis. On CTA, the false lumen is detected by the absent or diminished enhancement compared with the true lumen. Suspicion for dissection is raised in the setting of multiple apparent embolic strokes in a single carotid distribution or within the posterior circulation when there is a history of trauma, although spontaneous dissections are seen occasionally. As previously mentioned, the presence of emboli in multiple circulations raises the question of a more central etiology such as a heart valve vegetation.

Vasculopathy/Vasculitis

Acquired vasculopathies can be a result of known infectious or noninfectious causes or of unknown pathophysiology such as in primary cerebral vasculitis, which tends to involve medium and small vessels, or moyamoya syndrome, which demonstrates greatest involvement of the central cerebral vessels. Vasculopathy involving large and medium-sized vessels can be seen on MRA, although more subtle irregularities and small vessel involvement still requires a catheter angiogram, which remains the gold standard imaging modality.

In transient cerebral angiopathy of childhood, classically a basal ganglia infarct resulting from M1 MCA segment narrowing and occlusion of lenticulostriate vessels is seen, with cortical injury being less common. Narrowing typically of the terminal carotid and proximal M1 MCA segment of the affected side often can be delineated on MRA. A lack of well-developed collaterals also will be noted, in contrast to the typical presentation of moyamoya syndrome, where the vessel occlusion has been more slowly progressive over a longer period. Moyamoya "syndrome" denotes the pattern of vessel involvement that can be associated with type 1 neurofibromatosis, radiation injury, sickle cell disease, Trisomy 21 syndrome, or other pathology. When this pattern is idiopathic, the term moyamoya *disease* is used. More commonly, moyamoya syndrome/disease will be bilateral and MRI will demonstrate evidence of chronic ischemic insult. The enlarged lenticulostriate collaterals generally will be appreciable on both MRA (correlating with the "puff of smoke appearance" initially described with catheter arteriography) and as flow voids through the basal ganglia and basal cisterns on MRI (Fig. 63.11). These apparent flow voids need to be distinguished from enlarged perivascular spaces that also are seen in this region.

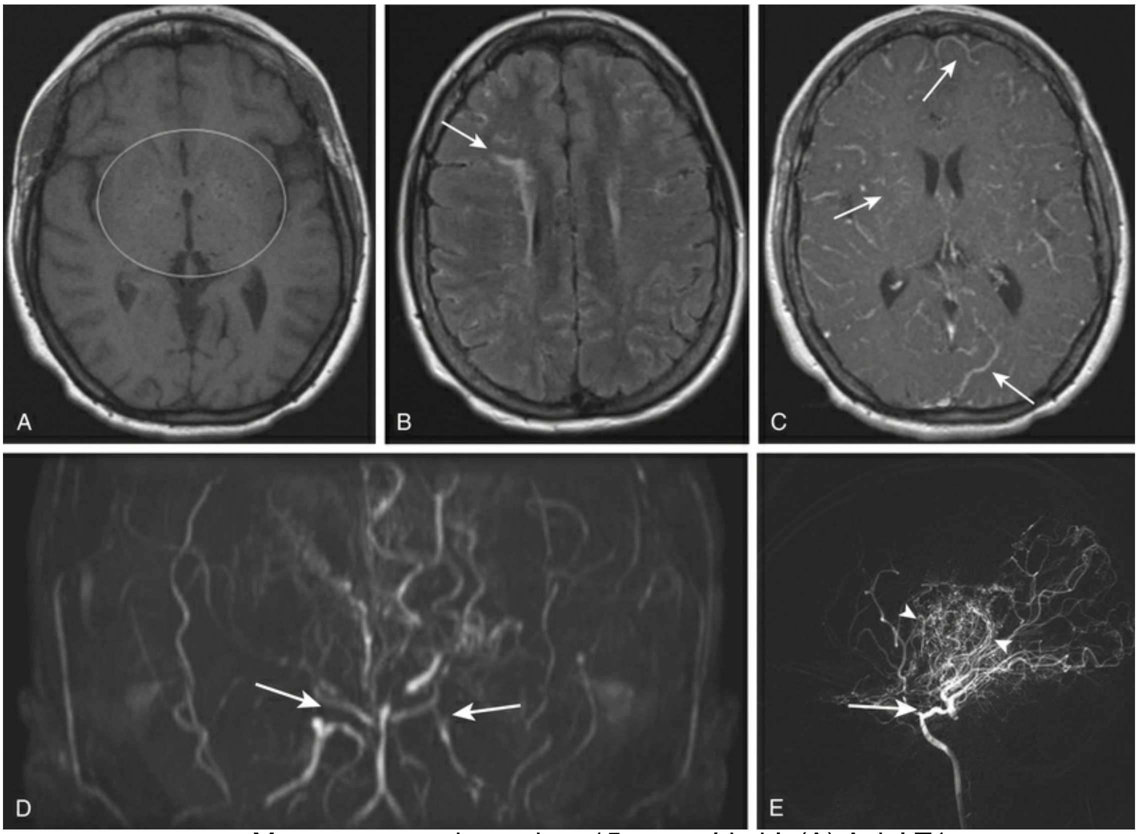

FIG. 63.11 Moyamoya syndrome in a 15-year-old girl. (A) Axial T1-weighted MR image shows flow voids *(circled)* associated with enlarged lenticulostriate collaterals. (B) Axial FLAIR image shows gliosis in the right anterior periventricular white matter *(arrow)* with leptomeningeal linear hyperintensities corresponding to collaterals. (C) Axial T1 postcontrast image demonstrates enhancing right lenticulostriate and leptomeningeal collaterals *(white arrows)*. (D) Coronal maximum intensity projection image from an MRA shows no flow distal to the terminal internal carotid artery and nonvisualization of right and left proximal posterior cerebral arteries (compare with normal frontal MRA image in Fig. 63.2). (E) Lateral view from a right ICA catheter angiogram showing occlusion of the ICA below the siphon *(arrow)* and extensive thalamostriate collateral vessels *(arrowheads)*.

Vasculitic changes can accompany infections including meningitis, either through direct invasion of vessels or by an immune response to the particular pathogen. Parenchymal injury, if present, is mediated by ischemic changes. The pattern of involvement in the immune-mediated mechanism may be fairly symmetric, as can be seen in acute disseminated encephalomyelitis (ADEM) or some metabolic diseases. Noninfectious vasculitides, including those associated with systemic disease—for example, systemic lupus erythematosus and, in particular, primary CNS vasculitis—can be more problematic in diagnosis. Classically, a catheter angiogram and occasionally a brain biopsy have been used to evaluate the possibility of primary CNS vasculitis. Most cases of symptomatic vasculitis will demonstrate abnormality on standard MRI (T2, FLAIR, and DWI) sequences, and thus a completely normal MRI makes the likelihood of CNS vasculitis low. Occasionally, however, there can be a vasculitic process in the presence of a normal MRI.[34] Furthermore, cases have been reported of biopsy-proved CNS vasculitis in

which the MRI was abnormal and results of a catheter angiogram were normal.[35] Because medium and small vessels often are involved in the setting of CNS vasculitis, to which MRA has less sensitivity, a catheter angiogram may be indicated in the setting of very strong concern for vasculitis with a normal MRA and occasionally even a normal MRI.

Vascular Malformations

Most arteriovenous malformations and aneurysms can be detected with a combination of MRI and MRA or CTA, although small lesions can be missed (Fig. 63.12). Catheter angiogram remains the gold standard for arteriovenous malformation diagnosis, confirming flow dynamics and the presence of intranidal aneurysms, and generally will be required before surgical intervention. In the appropriate clinical setting such as a spontaneous SAH without etiology, a negative MRI, MRA, or CTA, however, should not exclude a catheter angiogram. Arterial aneurysms are much less common in children than in adults, with many of those seen likely being congenital or due to infection in contrast to the typical acquired berry aneurysms seen in adults. As in adults, all but the smallest aneurysms can be seen on MRA or CTA, with CTA sensitivity for berry aneurysms in adult series reported in the range of 80% to 97%.[11] These studies, though, need to be of optimum resolution, are generally targeted to the high-risk locations for aneurysms in adults, and may not include less common aneurysm locations, which are seen with greater frequency in children. Angiographically occult lesions including capillary telangiectasia, cavernous malformation, and developmental venous anomalies are seen on MRI but usually are not of consequence except in cases of the occasional large cavernous malformation.

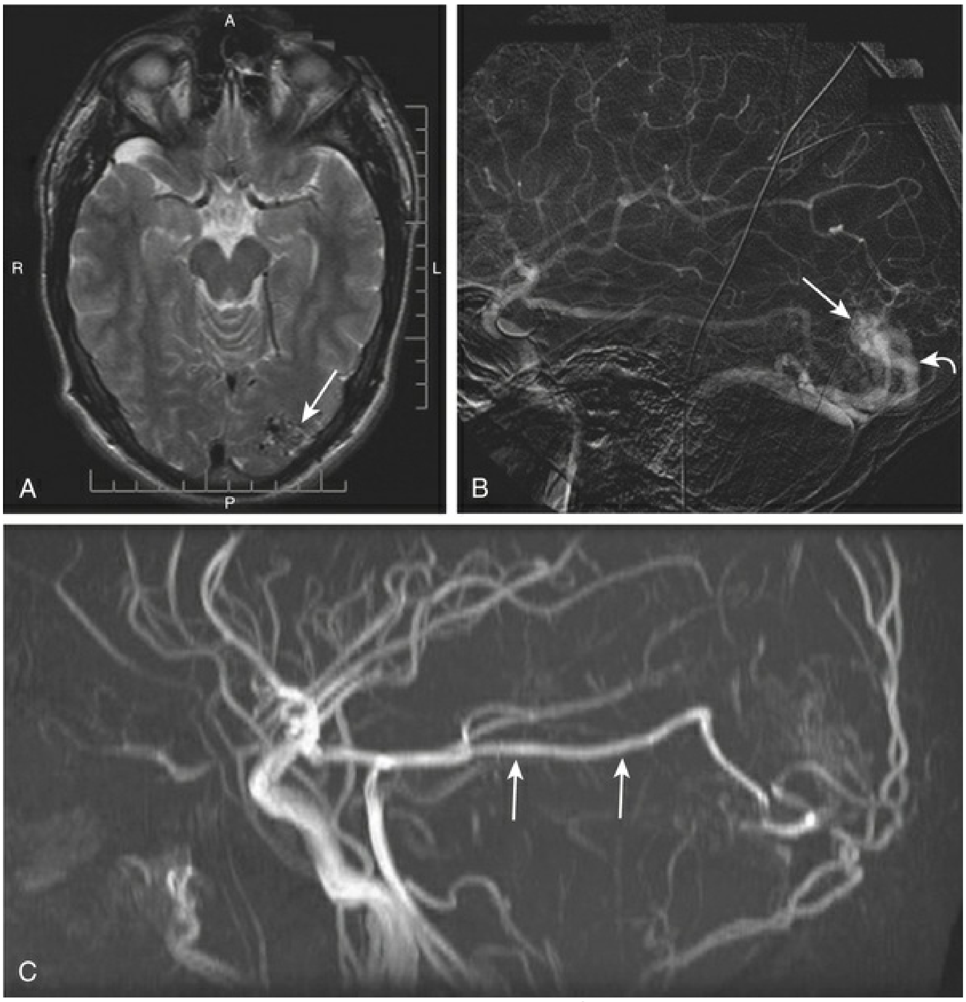

FIG. 63.12 A 14-year-old child with a left occipital arteriovenous malformation (AVM). (A) Axial T2-weighted MRI image shows multiple flow voids in the left occipital lobe *(arrow)*. (B) Lateral view from catheter angiogram confirms the presence of an AVM *(arrow)* and early draining veins *(curved arrow)*. (C) Lateral maximum intensity projection image from an MR angiogram shows an enlarged posterior cerebral artery branch *(arrows)*, which feeds the tangle of abnormal vessels.

A vein of Galen aneurysmal malformation (VGAM) is a misnomer because it is not the vein of Galen but a persistent embryonic vein that is dilated in association with a large fistula.[36] VGAMs presenting in the newborn period will manifest with cardiac symptoms resulting from the large shunt and high-flow congestive cardiac failure. Although the malformation can be seen with ultrasound, a CT scan is useful as a quick evaluation to visualize the malformation and determine the status of the cerebral cortex, which may be severely affected even at term. A noncontrast CT scan is sufficient because the density of blood (usually with an increased hematocrit) provides good contrast against the relatively less dense newborn brain (Fig. 63.13). In the presence of a VGAM, MRI with MR angiography will give an overall vascular road map for planning endovascular intervention, because the limited amount of contrast that can be used in a neonate necessitates directed intervention.

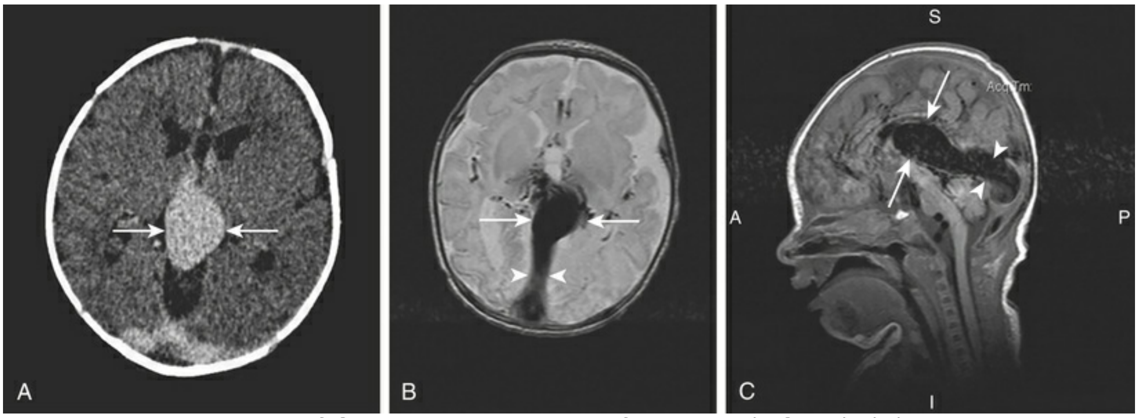

FIG. 63.13 Vein of Galen aneurysmal malformation (VGAM). (A) Axial noncontrast CT shows the dilated embryonic vein *(arrows)*. Axial T2 (B) and sagittal T1 (C) MRI demonstrates the dilated embryonic vein *(arrows)* and the draining vein *(arrowheads)*.

Central Nervous System Infection

Imaging findings and the role of imaging in cerebral infection will depend on the organism and location of the infection (see also Chapter 70). The appearance will depend on the cell type infected and the host immune response. Infection can involve the subarachnoid spaces and meninges, the parameningeal spaces, or the brain parenchyma itself either primarily or secondarily. With bacterial meningitis the appearance on CT and MRI may range from normal to diffuse swelling with loss of gray-white differentiation and obliteration of ventricular and cisternal CSF spaces. Coxsackie virus, echovirus, and mumps infect the meninges more than the neurons, whereas poliovirus infects the neurons, particularly the motor neurons. Herpes simplex virus type I has a predilection for the limbic system, most commonly affects the temporal lobes, and is the most common sporadic viral encephalitis.[37] Herpes simplex virus type II encephalitis is most commonly acquired at birth and does not display a predilection for the temporal lobes. Although MRI is more sensitive than CT, a normal MRI still does not entirely exclude viral encephalitis. In the clinical setting of suspected meningeal infection, CT may be indicated prior to lumbar puncture to exclude hydrocephalus or swelling that potentially would preclude lumbar puncture without neurosurgical consultation.

Imaging alone should not be used, however, to exclude meningeal infection. Particularly early in the setting of meningitis, contrast-enhanced CT is often normal. Although MRI with gadolinium is more sensitive, only 55% to 70% of persons with proved meningitis have abnormal CT or MRI scans.[38] Some investigators believe that CSF hyperintensity on the FLAIR sequence is more sensitive than gadolinium-enhanced T1-weighted sequence for meningitis; however, CSF hyperintensity on FLAIR associated with supplemental oxygen and anesthesia as well as noninfectious meningeal irritation and leptomeningeal tumor render this finding less specific.[39,40]

Complications associated with meningeal infection include compromise of the BBB leading to vasogenic edema, arterial spasm that can cause ischemia with cytotoxic edema and eventual infarction, and hydrocephalus potentially with the development of transependymal CSF flow/interstitial edema. Hydrocephalus can be

obstructive, typically at the level of the aqueduct (Fig. 63.14) or outlet of the fourth ventricle, or more commonly communicating because of impaired CSF resorption from arachnoid granulation obstruction with exudates. This impairment of CSF resorption can become permanent because of leptomeningeal-ependymal fibrosis and require shunting. Ultrasound can be used in very young patients; otherwise, CT and more recently half Fourier acquisition single shot turbo spin echo (HASTE) or other rapid, heavily T2-weighted MRI sequences usually are used to follow ventricular dilation. A primary role for imaging in meningitis is to evaluate for these complications. Two patterns of abnormal meningeal enhancement are seen on MRI with meningitis. A pachymeningeal pattern appears as diffuse linear thickening of the normal dural lining. This appearance, however, is not specific because the same pattern can be seen in other settings, including after surgery and occasionally following shunt revision, in some cases because of intracranial hypotension. The other pattern is a leptomeningeal enhancement, where enhancement is seen along the pia-arachnoid membranes, following the sulcal grooves. This pattern also is not specific, with a similar appearance being seen at times with leptomeningeal spread of tumor.

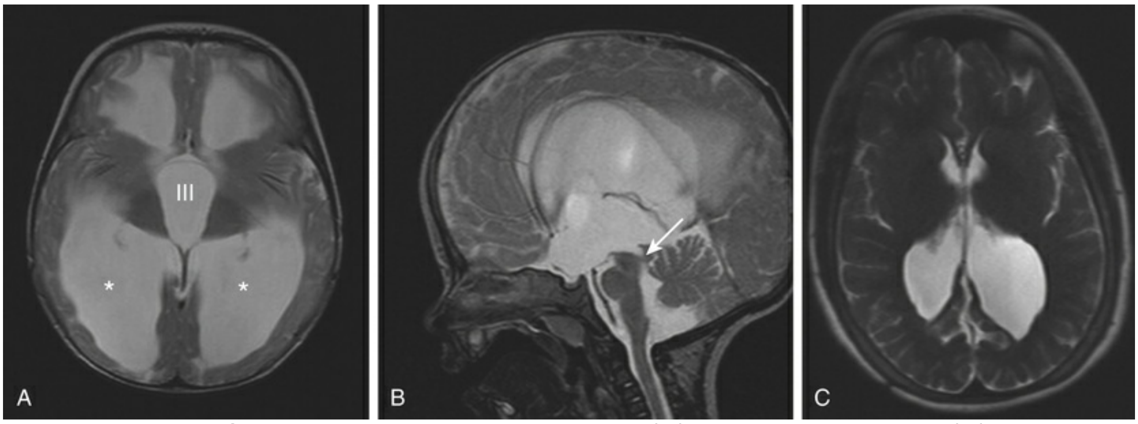

FIG. 63.14 Obstructive hydrocephalus. Axial (A) and midline sagittal (B) T2 MRI shows dilated lateral *(asterisks)* and third *(III)* ventricles that result from aqueductal obstruction *(arrow)*. (C) Chiari II malformation with hydrocephalus. Image demonstrates utility of heavily T2-weighted, half-Fourier acquisition, single-shot, turbo spin-echo MRI in evaluation of ventricles. Sequence can be obtained rapidly without the need for sedation; this avoids the radiation associated with repeated CT scans.

Extraaxial collections can develop in association with meningitis, including subdural effusions and, less commonly, subdural abscesses or empyema. Effusions are crescentic collections that typically are isodense to CSF on CT and isointense to CSF on most MRI sequences, although because the protein level may be increased, the collections may be hyperintense on T1 and FLAIR (Fig. 63.15). Subdural abscesses can be crescentic or lentiform when larger and typically slightly denser than CSF on CT. A rim of enhancement of variable thickness is generally better detected on MRI (Fig. 63.16). DWI can demonstrate restricted diffusion in subdural empyemas. Subdural (and brain) abscess also can occur as a direct extension of paranasal sinus or mastoid infection.

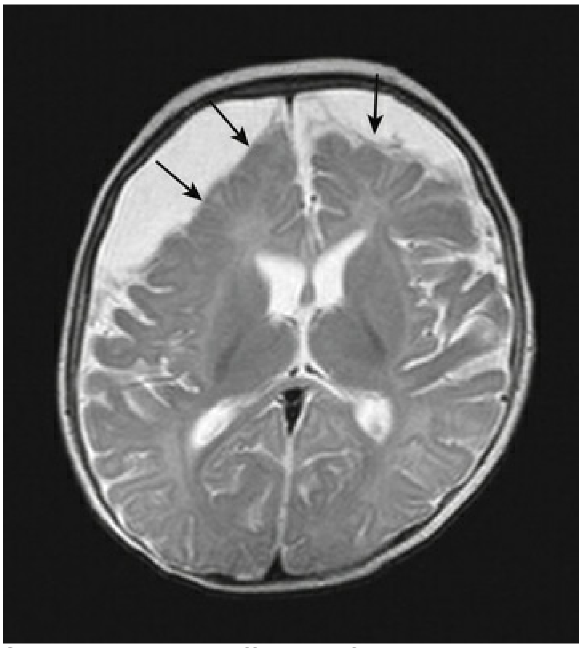

FIG. 63.15 Chronic subdural effusions following meningitis. Axial T2-weighted MRI shows mass effect with sulcal compression associated with bifrontal subdural collections *(arrows)*). Note that these subdural collections can be differentiated from enlarged subarachnoid spaces because the latter would have bridging vessels crossing the CSF in the subarachnoid spaces.

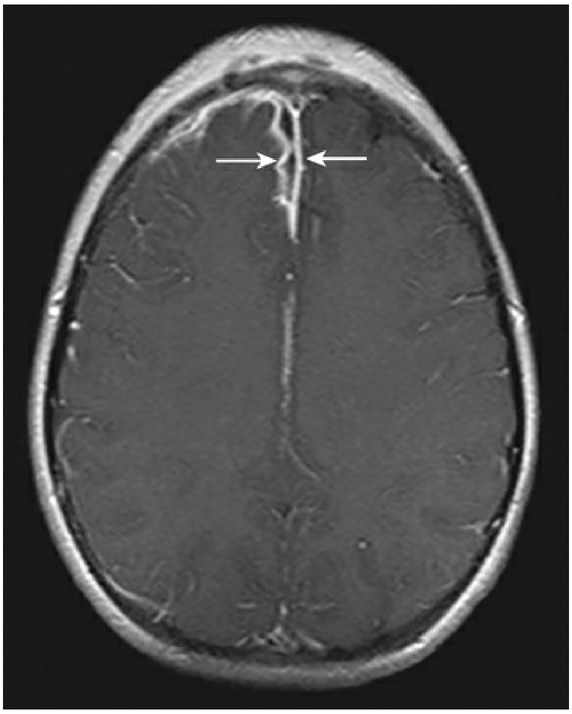

FIG. 63.16 Subdural abscess or subdural empyema. Axial T1-weighted MRI with gadolinium demonstrates a small rim-enhancing right frontal paramedian subdural abscess *(arrows)*. This area was restricted on DWI (not shown).

Infection of the brain parenchyma can take the form of a focal abscess(es) or a more diffuse encephalitis. Encephalitis in isolation or associated with meningitis generally will produce nonspecific cerebral parenchymal changes or cerebritis that appear bright on T2 and FLAIR sequences. Differentiation of cerebritis from ischemic changes associated with meningoencephalitis by imaging is problematic, especially because cerebritis also can demonstrate restricted diffusion. Areas of cerebritis evolve into focal abscesses that will generally demonstrate a central focus of low density on CT and low T1, high T2, and FLAIR signal on MRI, with a ring of enhancement and variable surrounding edema (Fig. 63.17). More commonly in adults with a ring-enhancing lesion, there can be uncertainty between a brain abscess and necrotic tumor. The brain abscess generally will have a thinner rim of enhancement, and on DWI a pyogenic abscess will demonstrate restricted diffusion. The necrotic tumor often shows a thick, irregular rim with increased diffusion or T2 shine-through. In differentiating pyogenic, tubercular, and fungal abscesses, some studies have described a greater likelihood of homogeneous diffusion restriction with pyogenic and tubercular abscesses but a variable pattern with fungal abscesses.[41,42] Exclusion of a meningeal or parameningeal abscess in the head can be accomplished largely with contrast-enhanced CT, looking for a fluid collection with a surrounding enhancing rim, although occasionally a small collection may be missed on CT but detected by MRI. Evaluation for meningeal or parameningeal abscess in the spine should be approached with MRI.

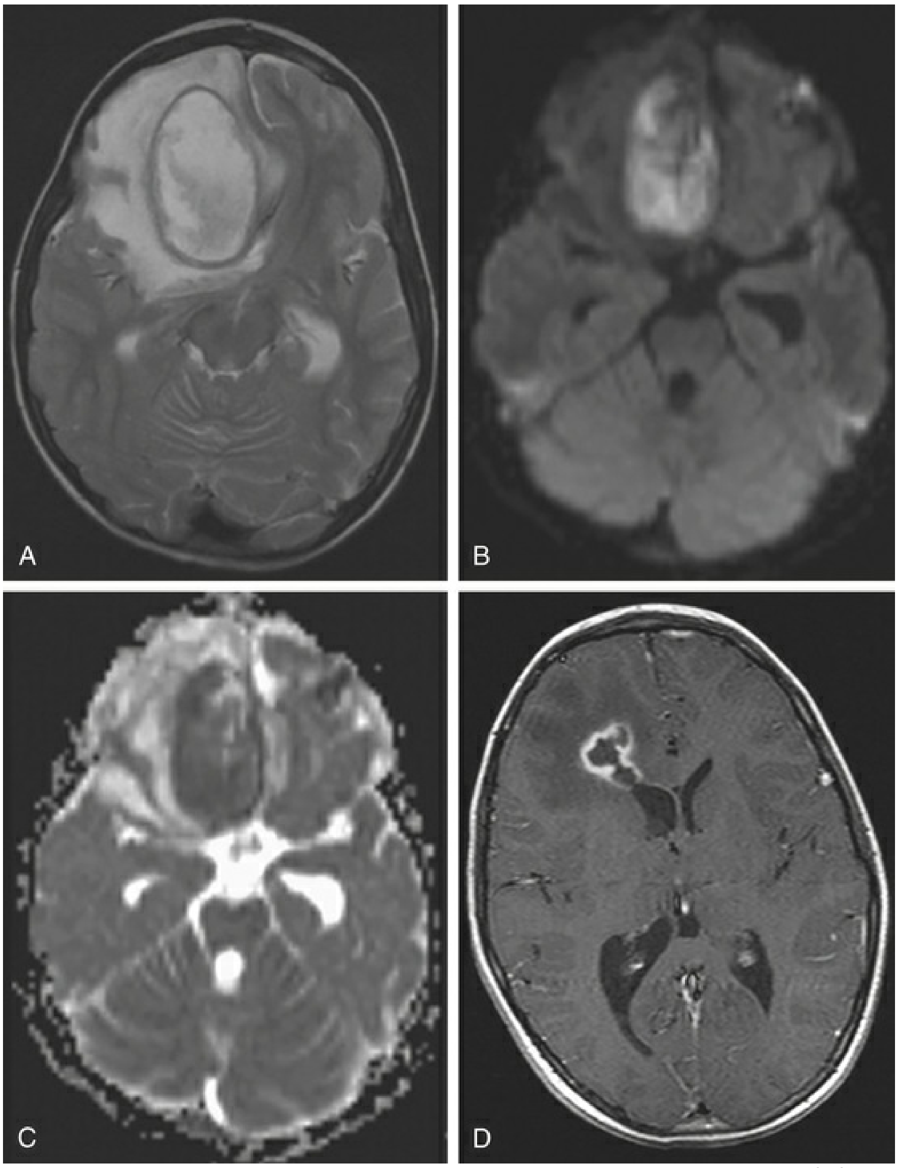

FIG. 63.17 Frontal brain abscesses. Axial T2-weighted MRI (A) demonstrates a right frontal ring-enhancing lesion with a T2 hypointense capsule that has considerable surrounding vasogenic edema and leftward midline shift. The lesion is bright on diffusion (B) and dark on the apparent diffusion coefficient map (C), suggesting that it is diffusion restricted. (D) In another patient, axial postcontrast T1-weighted MR image demonstrates a right frontal periventricular ring-enhancing lesion with T1 hypointense vasogenic edema surrounding it.

Demyelinating Disease

Multiple sclerosis (MS) is much less common in children than in adults, whereas ADEM primarily occurs in children. ADEM can at times manifest with symmetric involvement of central gray matter (Fig. 63.18), with an imaging picture that overlaps with some metabolic diseases. In other cases of ADEM, lesions, typically in the cerebral white matter, can be scattered with a picture similar to vasculitis or embolic infarction. The appearance of MS and ADEM can be similar, though some

features such as the perivenule orientation (Dawson fingers) of lesions are more characteristic of MS. The presence of lesions of multiple ages would be consistent with MS (Fig. 63.19) rather than ADEM. Demyelinating lesions are seen most commonly in white matter but appear in gray matter as well. Acute demyelinating lesions demonstrate enhancement. Acute lesions also can demonstrate restricted diffusion, with an appearance on DWI that mimics an acute ischemic lesion. Often, however, the pattern of involvement is useful in distinguishing demyelinating disease from ischemic disease. The spinal cord can be involved with MS or ADEM (Fig. 63.20), although relatively rarely in isolation, hence imaging the brain to look for additional involvement can be useful in some cases to distinguish between a cord demyelinating process and infarct, which can have a similar imaging appearance.

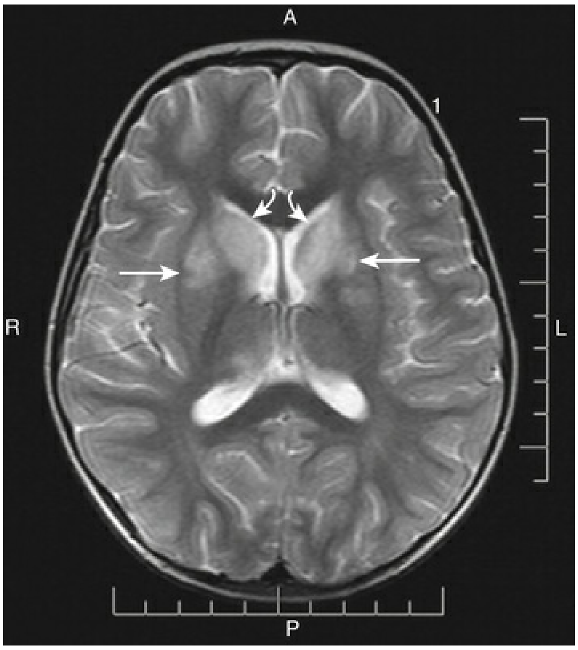

FIG. 63.18 ADEM. Axial T2-weighted MR image shows symmetric increased signal in the head of the caudate nucleus *(curved arrows)* and anterior lentiform nuclei *(straight arrows)* associated with ADEM.

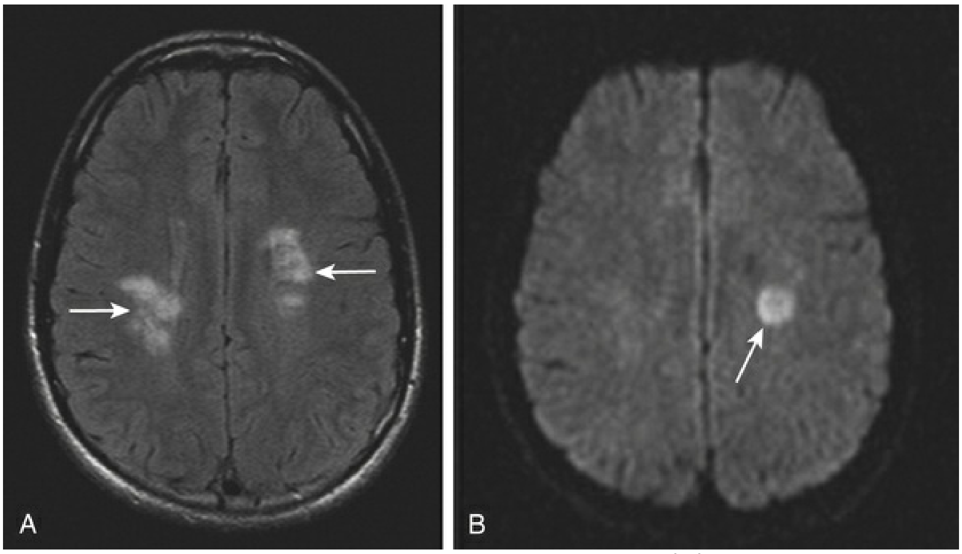

FIG. 63.19 Multiple sclerosis in a 16-year-old child. (A) FLAIR MRI shows bilateral white matter lesions *(arrows)*. (B) DWI demonstrates restriction of the left centrum semiovale lesion that was enhanced on postcontrast T1 MRI (not shown), suggesting an acute or active lesion *(arrow)*.

FIG. 63.20 Patient with clinical picture of transverse myelitis. Sagittal T2-weighted MRI of the distal cord shows central T2 hyperintensity within the conus medullaris *(arrows)* in this case of ADEM. An acute spinal cord infarct also could have this imaging appearance.

Trauma

CT remains the primary imaging modality in persons with acute cerebral trauma and has the advantage of relative ease of scanning compared with MRI, including speed of scanning and allowing non-MRI compatible monitoring and life support equipment to be used during imaging (discussed in Chapter 119). CT is usually sufficient for evaluation of most cerebral trauma requiring intervention, including assessment of swelling and acute hemorrhage within the intraaxial and extraaxial compartments. CT is generally more sensitive than MRI in detecting acute SAH and in the evaluation of bony injury (Fig. 63.21). CT is generally sufficient to detect cerebral swelling associated with herniation syndromes and therefore identify the potential need for neurosurgical intervention (Fig. 63.22). MRI is more sensitive for the detection of parenchymal injury and for more subtle extraaxial collections including more chronic subdural hematomas, a hallmark of inflicted traumatic brain injury associated with child abuse. MRI is indicated when there is doubt as to the presence of a subdural blood collection in the setting of suspected trauma. Also, in the setting of inflicted traumatic brain injury, MRI can detect evidence of old parenchymal or extraaxial hemorrhage not seen with CT using the GRE sequence (see Fig. 63.5D). In particular, gradient sequences and susceptibility-weighted imaging can reveal evidence of old parenchymal hemorrhages. Bony injury of the spine also is better evaluated with CT, although cord compression and injury are better assessed with MRI.

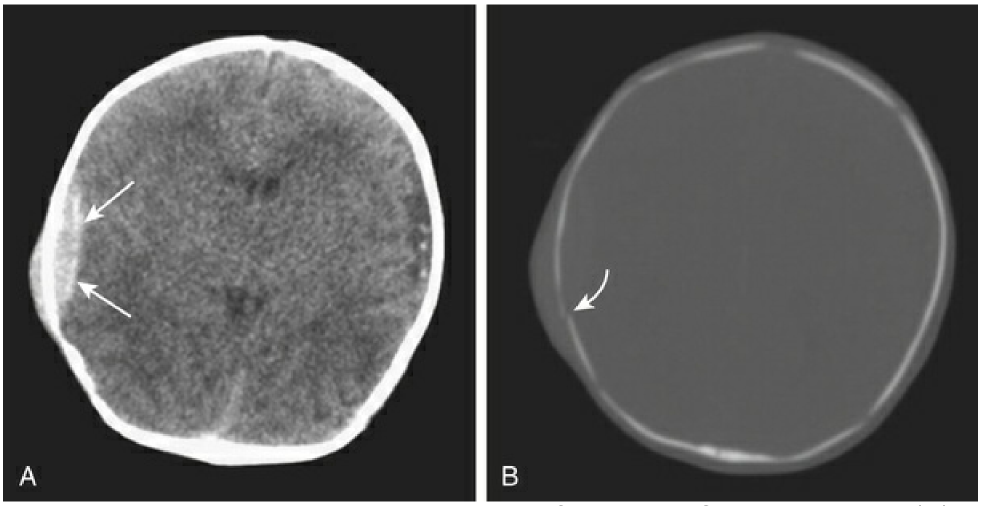

FIG. 63.21 Epidural hematoma with skull fracture. A CT scan in brain (A) and bone (B) windows shows the typical lentiform configuration of right-sided epidural hematoma *(arrows)*. The bone window reveals an associated fracture *(curved arrow)*.

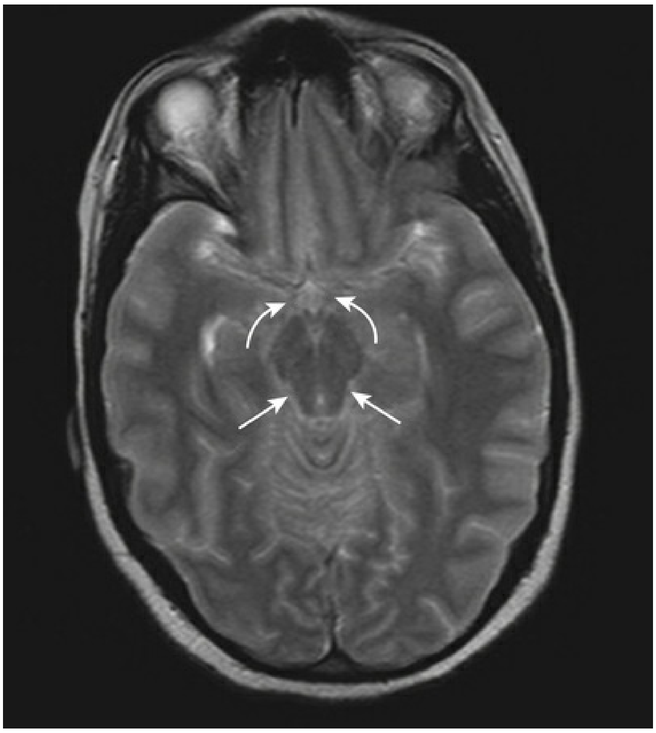

FIG. 63.22 Diffuse brain edema with herniation. T2-weighted MRI shows diffuse cerebral swelling with effacement of cerebrospinal fluid spaces associated with the ambient *(straight arrows)* and suprasellar cisterns *(curved arrows)*.

Hydrocephalus

Hydrocephalus can be congenital or caused by hemorrhage, tumor, and meningitis. In the neonatal period, ultrasound is used as a screening tool in evaluating for ventricular enlargement, in particular associated with germinal matrix hemorrhage. Beyond this period, most monitoring of ventricular size and shunts is accomplished with CT. Rapidly acquired heavily T2-weighted half Fourier acquisition single shot turbo spin echo MRI sequences have been used in the evaluation of hydrocephalus. These sequences can be obtained as individual slices in as little as 12 seconds on a 3.0 Tesla scanner and 19 seconds on a 1.5 Tesla scanner for the entire head and hence do not typically require patient sedation. Use of this technique offsets the radiation burden of repeated CT scans. In the initial evaluation of hydrocephalus, MRI can be helpful in determining the level and possible cause of CSF obstruction (see Fig. 63.14). Acute hydrocephalus can be associated with evidence of transependymal CSF flow across the walls of the ventricular system, better appreciated on MRI. The absence of this appearance, however, does not reliably predict the absence of increased pressure. Physiologic/functional evaluation of shunt patency is achieved with nuclear medicine shunt studies, as described previously.

Tumor

Cerebral tumors are best imaged with MRI (Fig. 63.23). Expedited evaluation of a cerebral mass can be accomplished in the acute setting with CT, which will

demonstrate the degree of mass effect and any impending herniation or midline shift. Posterior fossa tumors, which are more common in children and occur more often than supratentorial tumors in the 4- to 11-year age group,[43] and suspected acute spinal cord abnormalities, possibly associated with tumor, are best evaluated with MRI. CT is hampered by beam hardening artifact in the posterior fossa, at the skull base, and within the spinal canal.

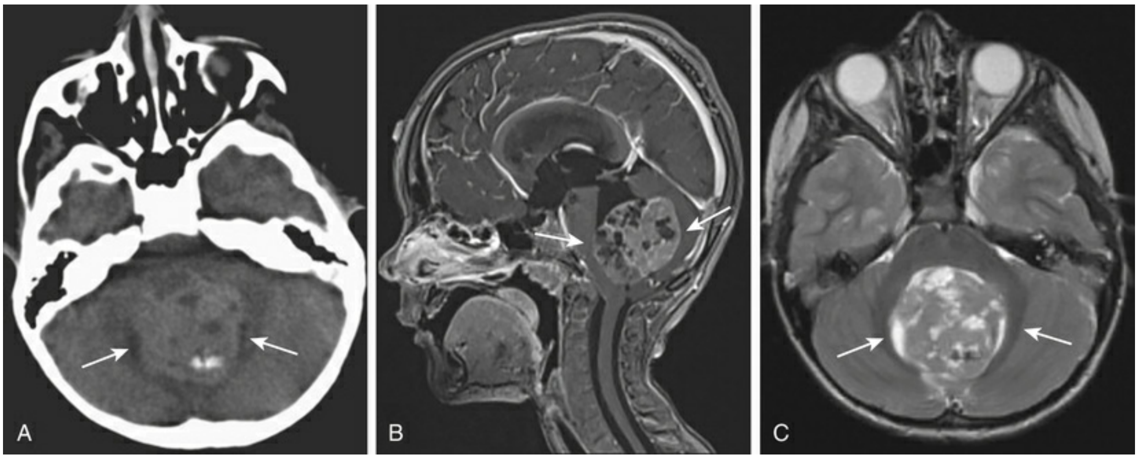

FIG. 63.23 Posterior fossa medulloblastoma. Axial noncontrast CT (A) and sagittal T1-weighted MRI with gadolinium (B) show a midline posterior fossa mass that has heterogeneous enhancement on postcontrast T1 and heterogeneous signal on axial T2-weighted MRI (C).

Seizures

The CT imaging yield for a single self-limited seizure with no focal neurologic deficit is low, although most children currently will ultimately be scanned with CT or MRI. With focal neurologic deficit or prolonged seizure activity, the imaging yield increases. As discussed in Chapter 67, after seizures are controlled, MRI is indicated in the absence of a clinically apparent etiology for the seizures. Acute abnormalities on MRI, however, may be secondary to rather than reflecting the underlying cause of seizures. Prolonged seizures can be associated with transient enhancement due to BBB disruption and cytotoxic edema with hyperintensity on DWI that may be confused with stroke. Positron emission tomography can also be used to identify epileptogenic foci by identifying areas of hypermetabolism.

Conclusion

The ultimate selection of imaging modality will depend on clinical question(s), age and condition of the patient, and the locally available imaging technology. Consultation with radiology colleagues is encouraged, and discussion of the clinical scenario and suspicions yields an appropriately tailored imaging protocol and a more relevant interpretation, which is becoming increasingly important with the ever-increasing complexity of imaging modalities.

CHAPTER 64

Pediatric Neurocritical Care

Michael J. Bell, Mark S. Wainwright

PEARLS

- Neurologic morbidity represents a major determinant of outcome among critically ill children. However, therapies that target specific cellular mechanisms of brain injury in children are lacking.
- Evidence that adult neurocritical care is a viable program in many centers largely rests with its widespread implementation. Such programs have demonstrated an association between their services and improved outcomes.
- Pediatric neurocritical care is no longer a new concept, and there are now published examples of approaches to its implementation and evolving evidence indicating that a neurocritical care service improves outcome.

Neurologic morbidity is a major determinant of outcome in critically ill children,[1] but therapies that target specific cellular mechanisms of brain injury in children with (for example) stroke, refractory seizures, or traumatic brain injury (TBI) are lacking. In the absence of data from randomized controlled trials, much of the clinical practice in the care of children with acute brain injuries or neurologic complications of critical illness is empiric. Moreover, the heterogeneity of disorders and subtleties of the clinical neurologic exam in the critically ill child are often beyond the scope of training for pediatric critical care, neurology, and neurosurgery programs. In response to these challenges, efforts have been made to develop programs to care for children with critical neurologic conditions with teams of dedicated specialists, generally pediatric intensivists and neurologists. These programs, called pediatric neurocritical care programs at present, depend on the ability of dedicated staff members to focus much (if not all) of their clinical and research endeavors toward common or uncommon neurologic conditions in order to improve outcomes for this vulnerable population of children.

This chapter (1) describes the evolution of pediatric neurocritical care as a clinical paradigm from a historical perspective, (2) outlines several rationales for embarking on this new organization of clinical care, and (3) describes challenges for the future

development of the discipline. Throughout this chapter and for simplicity, the phrase *adult neurocritical care program* will be used to describe neurocritical care programs developed to treat adults with neurologic disorders. This chapter will *not* review neurocritical care disorders or pathophysiologic principles, such as status epilepticus or the management of intracranial pressure, as these are comprehensively reviewed in other chapters of this text. However, studies of neurocritical care disorders that serve to argue for the further development of a neurocritical care focus in pediatric critical care will be discussed.

Historical Context

Advances in medical care have emerged either as a result of tectonic shifts of the mantel of the health care system or by incremental shifts of the landscape. As an example, military conflicts have contributed to cataclysmic changes in health care, from the development of lifesaving trauma surgical techniques (from the US Civil War to the current conflicts) to the development of effective triage systems for evacuating and treating wounded soldiers (culminating in improved systems developed during World War II through the Korean and Vietnam conflicts).[2] As a specialty, critical care medicine was a product of yet another seismic blast to the health care system—the polio epidemics that raged throughout Europe and the United States in the late 1940s and early 1950s. Advances in ventilation allowed survival from this debilitating affliction, culminating in the organization of the first intensive care unit at the Baltimore City Hospital in 1961 that was staffed by in-house physicians[3] (see also Chapter 1). The director of this first multidisciplinary intensive care unit was Dr. Peter Safar, a founding father of cerebral protection from cardiac arrest who advanced the field of neuroprotection for the duration of his career.

The subspecialty of neurologic critical care has evolved in a more gradual fashion compared to the specialty overall. Dr. D.W. Dandy is credited with developing the first neurosurgical intensive care unit for three patients at the Johns Hopkins Hospital in Baltimore in 1929, whereas the first fully staffed, large-scale neurocritical care unit was formed in 1969 at the University of Colorado by Dr. Michael Earnest.[4] Gradually, similar neurologic critical care units were established in many universities and tertiary care centers, paralleling the development of other subspecialty intensive care units (ICUs) for coronary, cardiovascular, surgical, pulmonary, and other conditions. Currently, neurologic critical care units can be further subdivided in many centers into neurotrauma, neurovascular, neurosurgical, and other specialties. In 2002, several dozen practicing neurointensivists formed the Neurocritical Care Society (with membership now numbering greater than 800) and held its first annual meeting in February 2003. In 2007 the United Council on Neurological Subspecialties offered the first examination in neurocritical care and accredited fellowship programs across the United States.

For pediatrics, caring for neurologically injured children was always at the forefront in establishing critical care programs. In their landmark paper from 1975, Downes and Raphaely[5] begin by writing, "The major objective of intensive care is to provide maximum surveillance and support of vital systems in patients with acute, but reversible life-threatening disease. In pediatric patients, the reversal of life-threatening conditions and preservation of essential functions, especially those of the

brain, may result in many years of useful life." During this time, Reye syndrome epidemics were commonly afflicting previously healthy children, and intensive neuroprotective measures were employed with increasing success to restore full neurologic function.[6]

These early years of pediatric critical care led to many advances including (1) management of respiratory failure (eg, the advent of surfactant for respiratory distress syndrome),[7,8] high-frequency oscillatory ventilation,[9] permissive hypercapnia, inhaled nitric oxide,[10] and extracorporeal membrane oxygenation (ECMO)[11]; (2) management of congenital heart diseases including palliative surgery (eg, Blalock-Taussig shunts[12] and the Norwood procedure),[13] definitive repair (eg, the arterial switch procedure for transposition of the great vessels[14] and the Fontan procedure),[15] and supportive care (eg, cardiopulmonary bypass[16,17] and ventricular-assist devices)[18,19]; (3) therapies for sepsis (eg, goal-directed resuscitation therapy[20] and the development of new antibiotics); and (4) supportive therapies for failing organs (eg, extracorporal life support, hemofiltration, hemodialysis, continuous renal replacement therapy, plasmapheresis/plasma exchange, and organ transplantation). The culmination of these and many other clinical advances have led to decreases in mortality in most pediatric critical care units to between 3% and 5%.

With this impressive reduction in mortality, the necessary next step in improving clinical care for critically ill children is to minimize morbidity. It is in this context that pediatric neurocritical care has emerged, as neurologic morbidity was seen as one of the greatest challenges to advancement of the field. In 2000 Dr. Robert Tasker[21] was among the first to write about a conceptual framework of multiple neurologic conditions that might benefit from particular expertise within pediatric neurocritical care when he provided an evidenced-based summary of three important neurologic conditions of critically ill children: the management of severe head injury, the use of benzodiazepines to treat status epilepticus, and the emergence of new forms of encephalopathies in children. In the intervening years, various groups have argued for the introduction of pediatric neurocritical care within the specialty of pediatric critical care medicine. The remainder of this chapter examines the various rationales for advancing pediatric neurocritical care programs and possible future directions for this effort.

Rationales for Development of Pediatric Neurocritical Care

Rationale 1: Sufficient Numbers of Children With Critical Neurologic Conditions Exist to Justify the Establishment of a New Service Specifically for This Population of Children

An important question for the development of pediatric neurocritical care programs involves an assessment of whether there are enough patients to justify the formation of this type of clinical service. As stated earlier, adult neurocritical care units and programs have been in existence for years and have therefore answered this question in the affirmative. During their early period, Bleck and colleagues[22] surveyed

admissions to their 14-bed, general medical intensive care unit and found that only 92 of 1850 admissions were related directly to neurologic conditions, mostly stroke and intracerebral hemorrhages. However, they found 217 patients experienced neurologic complications during the admission, including hypoxic/ischemic encephalopathy, seizures, metabolic encephalopathy, and stroke. A more recent analysis demonstrated that brain tumors, strokes, and subarachnoid hemorrhages accounted for more than 50% of admissions to neurocritical care units,[23] but the absolute number of admissions was not reported. In the intervening years, thrombolytic therapy for ischemic stroke, neurovascular procedures for aneurysmal subarachnoid hemorrhage, and the advent of comprehensive TBI and stroke teams have increased the need for intensively cared for adults. The evidence that adult neurocritical care is a viable program in many centers largely rests with its widespread implementation. Although the absolute number of neurocritical care units has not been collated, the United Council of Neurological Subspecialties (UCNS) has certified 60 programs in the United States and more than 1200 diplomates in neurocritical care (see http://www.ucns.org/globals/axon/assets/10301.pdf).

The predominant pediatric experience in subspecialty critical care program development comes from pediatric cardiac intensive care. Large pediatric institutions—Children's Hospital of Boston, Children's Hospital of Philadelphia, and the Hospital for Sick Children in Toronto as some of many examples—have long histories of cardiac intensive care programs.[24] These programs are based on the philosophy that the multidisciplinary team of cardiac intensivists, cardiologists, cardiac surgeons, anesthesiologists, neonatologists, and specially trained nursing and ancillary staff can more effectively treat the unique pathophysiology encountered in the correction of congenital heart disease. The viability of these programs is generally related to the volume of congenital heart surgery cases referred into the institution, and patients admitted to the hospital on this service are generally located in a unique space outside of the general pediatric intensive care unit. As of 2004, there were 132 pediatric cardiac intensive care programs and 250 members of the Pediatric Cardiac Intensive Care Society (PCICS) (http://www.pcics.org), indicating that these types of programs have certainly been viable for many institutions.

Four pediatric academic centers with neurocritical care services have reported their experience and patient volumes. LaRovere and Riviello described developing a pediatric neurocritical care service at Children's Hospital of Boston.[25] In 2006 they reported that 557 neurocritical care consults were obtained over a multiyear period. Little information is provided about the disorders treated and the role of the pediatric neurocritical care team in patient management. Therefore, it is difficult to discern the precise difference between this effort and an active neurologic consult service. At Children's National Medical Center, a neurocritical care consulting service consisting of an intensivist, two neurologists, and the neurosurgical staff was formed within the framework of the pediatric intensive care unit (PICU).[26] This service was designed to improve collaboration between the services and implement evidence-based guidelines for the care of children with TBI, stroke, status epilepticus, and other neurologic disorders. In a 14-month period, 373 neurocritical care consults were obtained among 1423 patient admissions. Approximately two-thirds of the consults were obtained in children with primary neurologic diagnoses

at PICU admission, but a substantial portion (34.1%) of the consults were obtained on children admitted with other medical/surgical conditions. The wide variety of diagnoses observed argued strongly that at least the three main specialties (intensivist, neurologist, and neurosurgeon) were required to make a comprehensive clinical team. Weaknesses of this study were the inability to determine if the consulting service led to improved outcomes for patients and lack of analysis on the financial viability of this model of care. A fully independent primary pediatric neurocritical care service staffed by intensivists with extensive neurologic experience began at the University of Pittsburgh in 2009. This service is staffed by attending physicians with experience in clinical or basic research in the field of neurologic injury. Within this service, children with neurosurgical and neurologic emergencies receive care, and protocol-driven research studies are conducted. At Ann & Robert H. Lurie Children's Hospital of Chicago, the neurocritical care service (comprising neurologists, an intensivist, and an advanced practice nurse) reported 1942 consultations over a 7-year period, constituting 19% of all PICU admissions.[27] Precise comparisons of patient volume across centers are not possible because reasons for neurologic consultations varied by institution. Overall the published pediatric experience suggests that 15% to 25% of children in the PICU may require evaluation by a neurocritical care service; however, these data are confounded by variations in institutional definitions of the criteria for mandatory or elective neurocritical care involvement.

Rationale 2: Development of Pediatric Neurocritical Care Programs Will Improve the Overall Outcome of Children Under Their Care

Any successful new program in critical care must lead to improved patient outcomes to justify changing existing approaches. At its basic level, improvements in mortality would provide the ultimate justification for such efforts, with concomitant decreases in neuropsychologic and neurologic morbidity also being important. Seminal work has indicated that adult or pediatric intensivist–led clinical teams are associated with improved outcome[28-31] and serve as models for future innovations in changes in care teams.

Adult neurocritical care programs have demonstrated an association between their services and outcomes in a variety of ways and for several medical disorders. In 2001 Mirski and colleagues[32] reported that admission to a "neuroscience intensive care unit" in a single institution was associated with improved outcome (decreased mortality and decreased length of stay) when compared to the similar institution prior to formation of this new ICU. On a larger scale, Diringer and colleagues[33] analyzed more than 1000 patients admitted with intracerebral hemorrhage from hospitals with and without neurocritical care programs. They found that patients admitted to hospitals without neurointensivists had a 3.4-fold increased risk of in-hospital mortality (OR 3.4; 1.65–7.6) after controlling for patient demographics, severity of intracranial hemorrhage, and hospital size. Varelas and colleagues[34] demonstrated that patients with stroke also benefited from neurocritical care programs. Specifically, in prospectively studying 433 stroke patients (174 admitted prior to neurocritical care unit development, 259 after unit development), they found

no difference in mortality between the groups but decreased length of stay across all stroke subgroups. Lastly, Josephson and colleagues[35] demonstrated that patients with subarachnoid hemorrhage treated in a neurocritical care setting had decreased length of ICU stay (12.4 days versus 10.9 days) and a decreased need for cerebrospinal fluid diversion (23% versus 11.5%) but no change in hospital mortality.

Data from the pediatric neurocritical care services at the University of Pittsburgh,[36] Northwestern University,[27] and from a national survey[37] suggest that critically ill children with primary CNS insults or neurologic complications of critical illness have a significantly increased risk for mortality compared to other children requiring ICU level of care. Neither of these groups reported the impact of their services on mortality. However, a landmark study from the Washington University St. Louis Pediatric Neurocritical Care Program showed that institution of its multidisciplinary neurocritical care service led to a significant reduction in mortality following severe TBI in children.[38] Other indirect evidence supporting the benefits of a protocol-driven, consistent approach to management of pediatric neurotrauma comes from a study examining the impact of adherence to Brain Trauma Foundation guidelines[39] for the management of severe pediatric TBI. In this study from five US centers, each 1% increase in adherence was associated with a 1% decrease in the change of poor functional outcome among survivors. Collectively, these findings suggest that, at least for severe TBI, a multidisciplinary, protocol-driven approach to management can significantly reduce mortality. Whether these findings apply to other pathologies is not known.

Importantly, there are no data that address the impact of any of the published pediatric experience with neurocritical care programs on long-term outcome and neurologic morbidity. It is clear from the authors' clinical experience at Pittsburgh and the precedent from studies of survivors of congenital heart disease[40] that identifying the true burden of neurologic morbidity after ICU discharge requires lengthy follow-up. Of the published pediatric neurocritical care programs only one currently includes long-term follow-up as part of the standard of care.[27]

Despite its significantly longer history, studies demonstrating improved mortality or morbidity after the institution of pediatric cardiac intensive care programs are limited. Data from an ICU survey linked to the Society of Thoracic Surgeons Congenital Heart Disease database did not find overall differences in mortality, ICU length of stay, or complications between 20,922 cardiac patients admitted to either a cardiac intensive care unit (CICU) or a traditional PICU.[40a] In moving forward, it will be important to demonstrate improvements in neurologic outcomes, which will be particularly challenging due to the variety of developmental stages of childhood. In assessing mortality, it will be important to avoid the limitations in the adult neurocritical care studies (comparison to historical controls) and to utilize expected mortality measured by standardized severity of illness measures (such as the Pediatric Risk of Mortality or other scoring systems).

Rationale 3: Advances in Care, Either Technologic or Experimental, Will Be Integrated More Effectively With a Pediatric Neurocritical Care Program Compared to the Standard Approach

Advances in the delivery of neurology-specific care, based on new technologies or standardized guidelines based on new evidence, continue at an increasing rate, and some have argued that this justifies a dedicated team of clinicians to provide such care. As outlined in other chapters within this text, the number of monitoring devices and technical advances for children with neurologic injuries continues to grow (see also Chapters 2, 66, and 67). Digitally acquired electroencephalograms (EEGs) and electronic interpretations that can be gleaned at the bedside in real-time, brain tissue oxygen catheters that provide second-to-second assessments of local cerebral oxygen tension, and noninvasive measures of regional brain saturations by near-infrared spectroscopy devices are now in routine use for children. Other techniques, including cerebral microdialysis and cerebral blood flow (CBF) devices (either catheters to assess local CBF or imaging studies to determine global CBF) are poised to be used in the coming years. Determining the correct combination of monitoring systems and implementing protocols to maximize their potential benefit and minimize possible harm are daunting challenges that all practitioners will face in the coming years. Suarez[41] proposed this argument as a justification for the widespread adoption of adult neurocritical services, and Chang[42] used it to support the development of pediatric cardiac intensive care programs.

Evidence-based guidelines for several neurologic disorders of children continue to emerge, and effective integration of these guidelines, along with technologic advances, into clinical practice in critically ill children will be an important challenge for clinicians. As examples, (1) the Brain Trauma Foundation published guidelines for the management of children after TBI in 2003 and these were revised in 2012,[43] (2) the American Heart Association published guidelines for caring for children after stroke (including the use of antithrombotic therapies),[44] (3) the American Academy of Neurology published a practice parameter to recommend treatment guidelines for children with status epilepticus,[45] and (4) the American Heart Association published guidelines on cardiopulmonary resuscitation and emergency cardiovascular care for children and neonates that includes opinions regarding the neuroprotective strategy of hypothermia.[46-48] All of these general guidelines have important consequences for caring for the critically ill child, and successful incorporation of these recommendations into clinical protocols within the ICU will be an important step in optimizing care.

Several clinical studies also outline the importance of rigorously controlled neuroprotective strategies and argue for specialists that might improve the chances of successful implementation. First, in one of the most significant studies in pediatric critical care, Hutchison and colleagues from the Canadian Critical Care Trials Group tested if early hypothermia—basically the only neuroprotective strategy currently available for testing—would improve outcome after severe TBI in children.[49] In a trial involving 225 children, there was a strong trend toward worse outcome in the treated group, including both death and poor neurologic outcome. However, the authors discerned significant methodological problems with the trial, including the increased number of children with hypotension, an increased incidence of vasoactive agents necessary during the rewarming phase, and an incomplete dose of hypothermia administered (approximately 16 hours based on data within the manuscript compared to 24 hours by the proposed protocol). Second, in a smaller study of a single center, Fink and colleagues[50] found that children receiving hypothermia for cardiac arrest had the same mortality rate compared to those

remaining normothermic in an uncontrolled audit of a single center. More important, they found that overshooting of target temperature was common (10% with rectal temperature of <30°C) in this non–protocol-driven care plan. Both of these studies argued that careful control of neuroprotective strategies is essential for both the safety of clinical trials and ultimately clinical care. The Therapeutic Hypothermia After Cardiac Arrest (THAPCA) out-of-hospital cardiac arrest trial reported no benefit of therapeutic hypothermia compared to therapeutic normothermia, in terms of the primary neurocognitive outcome measure, despite good temperature control in both treatment groups.[50a] In the future, in neuroprotective strategies for any of a number of neurologic conditions, it may be the role of the pediatric neurointensivist to effectively implement or provide oversight of the intervention.

Challenges, Controversies, and the Scope of Pediatric Neurocritical Care

The practice of brain-directed critical care in children faces specific challenges compared to that for adults. First, there are limited data to guide practice. For example, there are no randomized controlled trials to guide management of stroke, cardiac arrest, TBI, or refractory status epilepticus. Second, our understanding of the cellular mechanisms of injury in the developing brain is limited and the process for drug development slow. At present, there are no pharmacologic therapies available to the neurointensivist that target the primary cellular mechanisms of injury in, for example, TBI or stroke. Third, the mechanisms of CNS injury in children differ significantly from those in adults, and results of adult studies such as stroke cannot be extrapolated to children. The heterogeneity of disorders in critically ill children that lead to neurologic injury require that management be based on an understanding of fundamental cell biology and cerebral physiology with little evidence-based medicine to support management decisions. Last, the meaningful impact (other than survival) of any therapeutic interventions in children may take months or years to quantify.

Future of Pediatric Neurocritical Care

Pediatric neurocritical care is no longer a new concept, and there are now published examples of approaches to its implementation,[51-56,27] including evidence from the management of TBI that a neurocritical care service improves outcome.[57] There remains debate over staffing and leadership of this effort. Both intensivist-led[58] and neurologist-led approaches[27] have been proposed. Models including pediatric intensivist-led programs (Children's National Medical Center, the University of Pittsburgh Children's Hospital of Boston, and Washington University of St. Louis) and pediatric neurologist-led programs (Northwestern University and Baylor College of Medicine) exist currently. It seems likely at this juncture that an integrative approach with both of these services and neurosurgery will be required for the foreseeable future, as it is as unlikely that an intensivist-trained neurocritical care specialist will feel complete comfort in reading EEGs as it is for a neurologist-trained specialist to manage a critical airway. Although there are variations in structure and leadership by institution, the common theme is the collaborative

approach to patient care among the core disciplines of critical care, neurosurgery, and neurology. There is a supportable consensus that there is a need for a specific training program in pediatric neurocritical care,[52,53,59,60] as has been described in adult neurocritical care programs. This has been described as "cross-disciplinary training" between neurology and critical care.[60] The Northwestern Davee Program has adopted this approach with a neurocritical care fellowship program open to intensivists and neurologists, recognizing that conventional training in critical care or neurology is insufficient preparation for the complexity of the practice of pediatric neurocritical care,[27] and other programs are beginning to offer such opportunities.

The overall organization of pediatric neurocritical care in the future and the scope of its mission remain to be determined, and the authors would suggest that the essential components and disorders that may benefit from this approach are summarized in Tables 64.1 and 64.2. The experience of the pediatric stroke community also suggests that the collaborative multidisciplinary approaches taken by most centers can be successful.[61] Since the previous edition of this text, there is now evidence that a pediatric neurocritical care program can improve survival in an important subset of patients (TBI).[62] Whether the time and expense invested in these programs will help reduce the neurologic morbidity in pediatric critical illness is yet unknown and will require a commitment to the long-term care of these patients and the infrastructure to measure these outcomes. This is a substantial challenge.

TABLE 64.1

Essential and Ideal Components of a Pediatric Neurocritical Care Program

Organization	ICU Care	Follow-Up Care	Education	Administration and Support
Multidisciplinary team of neurologists and intensivists Specialty-trained APN with expertise in NCC Protected time for the NCC service Joint rounds with critical care Stable NCC team for consistency of care Responsible for neonatal, cardiac, and pediatric ICUs	Protocol-driven care Involvement of bedside nurses Iterative modification of care practices based on outcome data Internal guidelines based on best available preclinical and clinical research Use of all available monitoring tools (eg, NIRS, pupillometry, optic nerve ultrasound, brain tissue oxygen monitoring) 24/7 EEG monitoring with interpretation by the NCC service	NCC team follows patients in hospital after leaving the ICU Dedicated NCC follow-up clinic Staffed with neurologist, intensivist, physiatrist, and APN Outcome measures collected for all patients	Create a culture of brain-directed critical care Training rotations in NCC for fellows in critical care, psychiatry, and anesthesia Training rotation in NCC for APNs Weekly NCC teaching conference and joint conference with adult stroke and NCC teams Monthly NCC teaching conference Emphasis on the integration of ICU neurologic exam with fundamental cellular mechanism of cerebral injury	Department or hospital support, recognizing the need to protect team members' time Data collection for all patients used to link long-term outcome to ICU care and to modify practice Participation in multicenter studies Emphasis on publication and sharing of experience and protocols

APN, advanced practice nurse; *EEG*, electroencephalogram; *NCC*, neurocritical care; *NIRS*, near-infrared spectroscopy.

In summary, enthusiasm for the practice of pediatric neurocritical care continues to grow across the United States and abroad. At this time, university-affiliated pediatric critical care and neurology divisions have established or are starting clinical services in pediatric neurocritical care. In going forward, it is important to determine if these clinical programs affect important outcomes for children and which team structure allows for the best results. In their landmark paper, Safar and Grenvik[3] argued that a sequence of nine steps must be accomplished when building a successful critical care program: (1) planning and organization, (2) training in basic nursing/physician skills, (3) building and equipping the unit, (4) opening the unit, (5) developing special standards and protocols, (6) training nonphysician personnel, (7) continuing education of nurses/physicians, (8) developing full-time coverage, and (9) developing research programs. At present, step 3 may not be needed, as there is little effort to build self-standing neurocritical care units for children at this time. Nevertheless, it seems that many programs have accomplished a number of the eight remaining steps with some success. It remains to be seen how implementation of these programs will fare in the coming years and what advances in care may be obtained.

CHAPTER 65

Coma and Depressed Sensorium

Tony Pearson-Shaver, Renuka Mehta

PEARLS

- A Glasgow Coma Scale score less than 15 in children should be taken seriously.
- The ABCs (airway, breathing, and circulation) should be the priority during management of a child with coma.
- A spinal tap should be deferred until the possibility of raised intracranial pressure has been ruled out.
- The patient's blood glucose level should be checked with urgency during the initial presentation of coma.
- When in doubt, it is better to protect the airway and prevent hypoxemia and hypercarbia electively.
- Unequal size of the pupils can be a sign of uncal herniation.
- The goal of therapy should be the prevention of secondary brain injury.

Coma, a state of unresponsiveness and unconsciousness, presents in many disorders ranging from structural central nervous system (CNS) injuries to diffuse systemic abnormalities. As a medical emergency, coma presents a challenge to providers because optimal care requires timely intervention; however, information is frequently limited during the initial evaluation. Knowledge of CNS anatomy and structures responsible for consciousness provides helpful clues as one attempts to interpret physical findings and optimize patient care. A careful general physical examination with a focused neurologic examination can suggest the diagnosis, aid in the location of lesions, guide therapeutic intervention, and determine prognosis. Further adjunctive radiologic and laboratory evaluation will then confirm physical findings. This chapter therefore considers CNS anatomy, the pathophysiology of coma, historical and physical findings that aid in the localization of lesions, the emergent management and evaluation of patients presenting with an altered level of consciousness, and the prognosis of patients who present with coma.

Pathophysiology

The brain tolerates only limited physical or metabolic injury. Coma implies advanced brain failure, and the longer the brain failure lasts, the greater the possibility that the injury will result in permanent neurologic impairment. Coma may be described simplistically as a lack of consciousness. Posner and colleagues[1] described coma as a "state of unresponsiveness in which the patient lies with eyes closed and cannot be aroused to respond appropriately to stimuli even with vigorous stimulation." Comatose patients may grimace in response to pain and the extremities may move in stereotypical withdrawal patterns, but the patient cannot localize responses or make defensive movements. As a coma deepens, responsiveness even to painful stimuli may be lost. Because motor reflexes are preserved, the depth of a coma cannot be assessed based only on motor responses. In many comatose patients, reflex movements will develop in response to stimuli. The depth of coma is best assessed by the patient's level of consciousness.

Consciousness is a set of neural processes that allows an individual to perceive, comprehend, and act on and in the internal and external environment.[1] Two neurophysiologic functions, *arousal* and *awareness,* which rely on discrete neuroanatomic locations, are integrated in the conscious person.[2] *Arousal* or *wakefulness* describes the degree to which an individual appears to be able to interact within the environment. *Awareness* reflects the depth and content of the arousal state. When one is aware, one is alert (or aroused) and cognizant of self and surroundings. The relationship between wakefulness and awareness is hierarchical: Awareness cannot occur without wakefulness, but wakefulness may be observed in the absence of awareness (eg, sleep/wake cycles in a vegetative patient).

Sleeping and waking are common examples of different states of arousal. Although coma and sleep both abolish conscious interaction with the environment, they differ physiologically because sleep is an active physiologic process with several distinct stages, and mechanisms for arousal remain intact. Sleep is dominated by a cortically generated slow wave (electroencephalogram [EEG]) activity within networks of neurons and glia, modulated by extracellular ion currents. Wakefulness is produced through the activation of brain stem and basal forebrain structures that disrupt sleep oscillations and elicit a global change in extracellular ion flow that modifies glial and cerebral blood flow. Coma, however, occurs as a result of an impairment of physiologic components responsible for arousal and an inability to consciously interact.[3-5]

Anatomy of Arousal and Ascending Reticular Activating System

Arousal occurs by physiologic mechanisms that can be selectively impaired by toxins, anesthetics, or physical destruction of the brain stem. Neuroanatomically, the ascending reticular activating system (ARAS) and related structures responsible for arousal are primarily located in the brain stem in the paramedian tegmental gray matter immediately ventral to the pons. Three ARAS principal pathways have been identified (Fig. 65.1). Communications have been identified between the ARAS and the cortex and the limbic system via the thalamic reticular nucleus, the cortex

hypothalamus, the basal forebrain, and the brain stem median raphe (locus caeruleus).[3] Because the ARAS receives collaterals from and is stimulated by every major somatic and sensory pathway directly or indirectly, it is best regarded as a physiologic rather than an anatomic entity. This partly explains why patients with very large discrete lesions (brain tumors) may be entirely alert, whereas patients with anatomically undetectable but biochemically widespread lesions (eg, hepatic encephalopathy) may be deeply comatose.

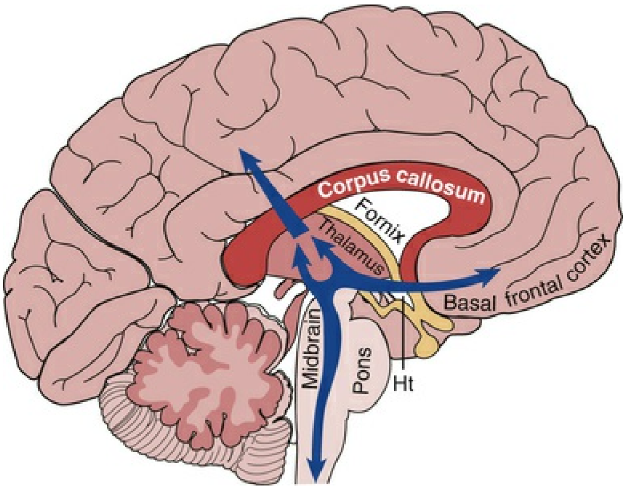

FIG. 65.1 Reticular activating system. (Modified from Hudson AJ. Consciousness: physiological dependence on rapid memory access. Frontiers Biosci 2009;14:2779-2800, 2009.)

Primarily, two types of lesions depress the level of arousal: direct brain stem–diencephalic injury involving the reticular formation and nuclei, or bilateral cerebral hemisphere dysfunction. Consequently, conscious behavior depends on the interplay between the cerebral cortex and the ARAS because these neural components are required for arousal and to maintain awareness.[1,3] Because the brain maintains a rich network of connections among the cortex, the ARAS, and the brain stem, patients with large discrete lesions might be alert on presentation, although localized neurologic deficits are noted on physical examination. On the other hand, patients with only minimal exposure to CNS depressants present with a depressed sensorium. Changes in a patient's level of consciousness imply significant dysfunction and can occur with variable degrees of wakefulness.

States of Impaired Sensorium

Precise definitions and descriptions of the various levels of consciousness are helpful in establishing a baseline, communicating with other health care providers, and interpreting changes in a patient's condition. Box 65.1 describes definitions for varying levels of consciousness; however, many terms used to describe alterations in sensorium lack precision and are better avoided. Colloquial use of the terms *lethargy, obtundation, somnolence,* and *stupor* have rendered them imprecise, and health care workers are best served to avoid them when describing patients with altered consciousness. Numerous scoring systems have been developed to assess acute neurologic conditions. By far the most common is the Glasgow Coma Scale score

(GCS). Developed to classify the depth of coma in adults who have sustained a head injury, the use of the GCS has been expanded to evaluate patients who have sustained a variety of neurologic injuries. A GCS score of 8 or less has been used as an alternative definition of coma. Although other scales are used to assess the severity of illness in coma (eg, Liege coma scale, Apache II scale, and Reye syndrome), the GCS has gained wider acceptance because of its ease and familiarity. A modified GCS has been devised that is more applicable to infants.

Box 65.1

Traditional Definitions of Levels of Consciousness

1. Clouding of consciousness—impaired capacity to think clearly and to remember current stimuli
2. Delirium—disturbed consciousness with motor restlessness, disorientation, and hallucination
3. Obtundation—reduced alertness; appears to sleep but responds to verbal or tactile stimuli
4. Stupor—markedly reduced alertness; only responds to noxious stimuli
5. Coma—no response to even noxious stimuli and will not utter understandable words

Several states of depressed consciousness are described and deserve mention. Consciousness disorders should be distinguished from *brain death*, an irreversible loss of all brain and brain stem function.[6,7] *Coma* is a state characterized by the absence of arousal and awareness. To differentiate coma from more transient causes of depressed sensorium (eg, syncope and concussion), coma must last more than 1 hour. Comatose patients do not speak, open their eyes spontaneously, follow commands, move spontaneously, or respond meaningfully to painful stimuli. Spinally mediated stereotypical movements may be made in response to pain, but patients do not actively withdraw. Sleep-wake cycles are not preserved in patients who are in a coma. Patients in a coma are in a transitional state and can either deteriorate to a more permanent state of depressed sensorium, deteriorate to fulfill brain death criteria, or recover.

Identification of Cause

Coma may present as part of the progression of a known neurologic illness or the unpredictable consequence or complication of a known systemic disease, or it may result from a totally unexpected event or illness.[7] An accurate history of the events and circumstances before the onset of the symptoms and information concerning the patient's medical history and use of medications may be invaluable in determining the cause of coma and quickly lead to the most appropriate diagnostic testing and treatment. As with most pediatric disease, the differential diagnosis of coma is age

related as described in Table 65.1. Common etiologies of coma seen in the pediatric population are described in Box E65.1.

Initial Assessment and Immediate Resuscitation

The initial assessment of the comatose patient should start with an evaluation of airway patency, the adequacy of ventilation, and the patient's hemodynamic status. Appropriate life support intervention should occur whenever a life-threatening illness evolves throughout the assessment. Measurement of core temperature is an important adjunct. Many practitioners assign an initial GCS score at this time.

It is important to observe the respiratory pattern. The rate and regularity of respiration depends on a complex interplay of chemical and neural control systems that operate automatically to reset the rate and depth of breathing as changes occur in gas tensions and pH. In the comatose patient, abnormality may occur in rate and in the pattern. A low respiratory rate is associated with CNS depressants—for example, alcohol, barbiturates, benzodiazepines, and narcotics—and leads to hypoventilation. It also can be associated with elevated intracranial pressure (ICP). Tachypnea is far more commonly due to a physiologic response to hypoxia, metabolic acidosis, or fever, but central hyperventilation can be a sign of brain stem herniation.

The hemodynamic disturbance and hypotension leading to shock that occur coincident with coma are mainly seen in systemic diseases (eg, sepsis, drug ingestions, myocardial injury, and adrenal insufficiency), but it is not uncommon to see neurogenic shock related to severe traumatic brain injury (TBI) and spinal cord injury as well. Hypertension in a comatose patient suggests an intracranial structural lesion and raised ICP, but it may be causative related to primary hypertensive encephalopathy.

Once the patient's airway, breathing, and hemodynamics are stabilized, a complete general examination and specific neurologic examination should be performed and any signs of trauma noted. Cervical immobilization should be maintained until trauma has been excluded and the cervical spine has been cleared by radiographic and physical examinations. The patient should be completely exposed to allow a visual appraisal of swelling, lacerations, bruises, and other obvious signs of trauma. Blood or clear fluid noted in the nose or ears suggests a basilar skull fracture. Injuries with characteristic patterns (eg, cigarette burns and glove and stocking burns), characteristic shapes, and characteristic locations (eg, finger marks on the buttocks and bruises over ear lobes) suggest child abuse (see also Chapter 122).

Focused Neurologic Examination

A focused neurologic examination is key to documenting a baseline neurologic status and helps to locate lesions and determine prognosis in patients with a diminished level of conscious (LOC). Because a diminished LOC requires either ARAS or bilateral hemispheric dysfunction, testing the structures immediately adjacent to the ARAS provides clues to the etiology of coma and directs subsequent investigations. A thorough physical examination must be systematic and is as

valuable as radiographic and laboratory studies. The neurologic examination of a comatose patient differs from that of an awake, communicative subject and involves pupillary response, respiratory pattern, stimuli required to illicit a motor response, and the general character of the responses. History and presenting symptoms should be evaluated in the context of neurologic findings. Taken together, the history and presenting symptoms help determine the cause of diminished LOC. The level of neurologic dysfunction can often be defined clinically by the respiratory pattern (Table 65.2), associated eye findings, and motor examination (Table 65.3).

TABLE 65.2

Respiratory Patterns in Patients With Altered Mental Consciousness

Pattern	Description	Localization
Posthyperventilation apnea	Apnea for >10 seconds after 5 deep breaths	Bilateral hemispheric dysfunction
Cheyne-Stokes respiration	Rhythmic waxing and waning of respiratory amplitude	Bilateral hemispheric dysfunction
Central reflex hyperpnea	Continuous deep breathing	Bilateral hemispheric (eg, trauma), lower midbrain, upper pons
Apneustic respiration	Prolonged aspiratory time (“inspiratory cramp”)	Pons
Ataxic respiration	Infrequent irregular breaths	Lower pons or upper medulla
Ondine's curse	Failure of involuntary respiration with retained voluntary respiration	Medulla
Apnea	No respiration	Medulla down to C4: peripheral nerves, neuromuscular junction

TABLE 65.3

Differentiating Characteristics of Structural and Metabolic Coma

Supratentorial Lesions	Infratentorial Lesions	Toxic, Metabolic, or Infectious Processes
Initial focal signs Retrocaudal progression Asymmetric examination often present early	Brain stem abnormalities often initial signs Sudden onset of coma Cranial nerve abnormality often seen Respiratory pattern often altered, such as central reflex hyperpnea	Confusion/stupor often precede signs Symmetric examination Pupillary reactions preserved Respiratory rate often altered, such as Cheyne-Stokes breathing

Respiratory Pattern

Breathing abnormalities in rate, depth, or regularity are associated with altered LOC. These abnormalities could be signs of drug overdose, increased ICP, or herniation. Observance of the respiratory pattern also can assist in localizing a lesion. Anatomic correlations between areas of injury and the resultant respiratory patterns are found in Table 65.2 and Fig. 65.2.

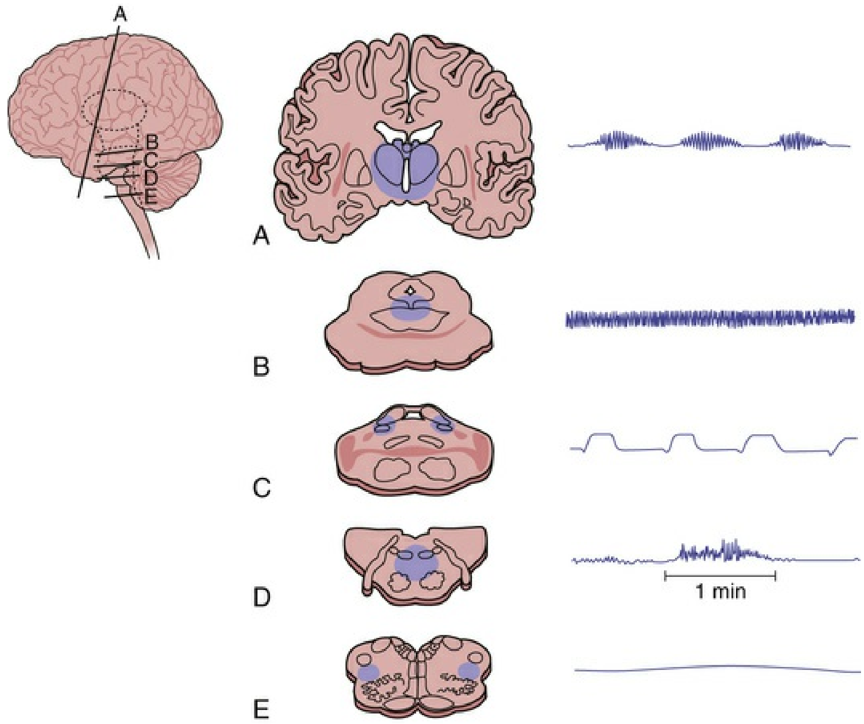

FIG. 65.2 Respiratory patterns and associated levels of injury. (A) Cheyne-Stokes respiration is seen with metabolic injury and lesions in the forebrain and diencephalon. (B) Central neurogenic hyperventilation is most commonly seen with metabolic encephalopathies. (C) Apneustic breathing (inspiratory pauses) is seen in patients with bilateral pontine lesions. (D) Cluster breathing and ataxic breathing are seen in lesions at the pontine medullary junction. (E) Apnea occurs when the medullary ventral respiratory nuclei are injured. (Modified from Posner JB, Saper CB, Schiff ND, et al., eds. The Diagnosis of Stupor and Coma. 4th ed. New York: Oxford University Press; 2007.)

Eye Examination

Specific eye findings can help localize the level of lesions and establish prognosis. Pupillary changes are informative during the examination of coma because the brain stem areas that control consciousness are adjacent to those that control pupillary response. It is important to distinguish between pupillary dilatation caused by disease or injury and that caused by medication. Pupillary changes due to structural lesions depend on the site of the primary lesion and secondarily on the effects of increased ICP as described in Table 65.3 and presented in Fig. 65.3. Because pupillary pathways are relatively resistant to metabolic insults, the presence or absence of a light reflex is the single most important physical finding that distinguishes structural from metabolic disease. Any reactivity is indicative of intact pathways and would rule out brain death.

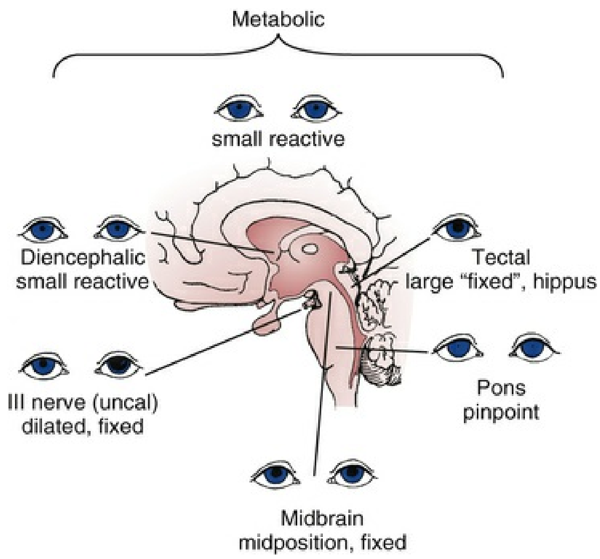

FIG. 65.3 Pupils in comatose patients.

Pupillary size is the result of a balance in tone between two opposing muscle groups of the iris: the dilator pupillae and the sphincter pupillae muscles. The dilator pupillae is responsible for dilation of the pupils under the control of sympathetic nerve fibers. The sphincter pupillae muscle is responsible for constriction of the pupils under control of parasympathetic nerve fibers. Pupillary size is regulated by reflex mechanisms that occur as a result of ambient light. Size is further affected by age, emotional state, state of arousal, and intraocular pressure.

Anatomically, the pupillary light reflex requires a four-neuron pathway. Light information from retinal ganglion cells travels through the optic nerves, the optic chiasm (where the nasal fibers decussate), the optic tracts, and synapse in the pretectal nuclei of the dorsal midbrain. Pretectal nuclei receive input from both eyes and send axons to both Edinger-Westphal nuclei. The contralateral innervation of the Edinger-Westphal nuclei is the anatomic basis for the consensual light response.

Pupillary constriction occurs as a result of parasympathetic activity (Fig. 65.4). Parasympathetic nerve fibers travel along the third cranial nerve to the ipsilateral ciliary ganglion within the orbit. The pupillary sphincter muscle (and ciliary muscle for lens accommodation) is innervated by the postganglionic parasympathetic fibers. Pupillary constriction to near stimuli occurs as a result of parasympathetic fibers that descend from higher cortical centers directly to the Edinger-Westphal nuclei, bypassing the pretectal nuclei in the dorsal midbrain. This redundancy explains the preservation of the near response when the dorsal midbrain and pretectal nuclei are injured.

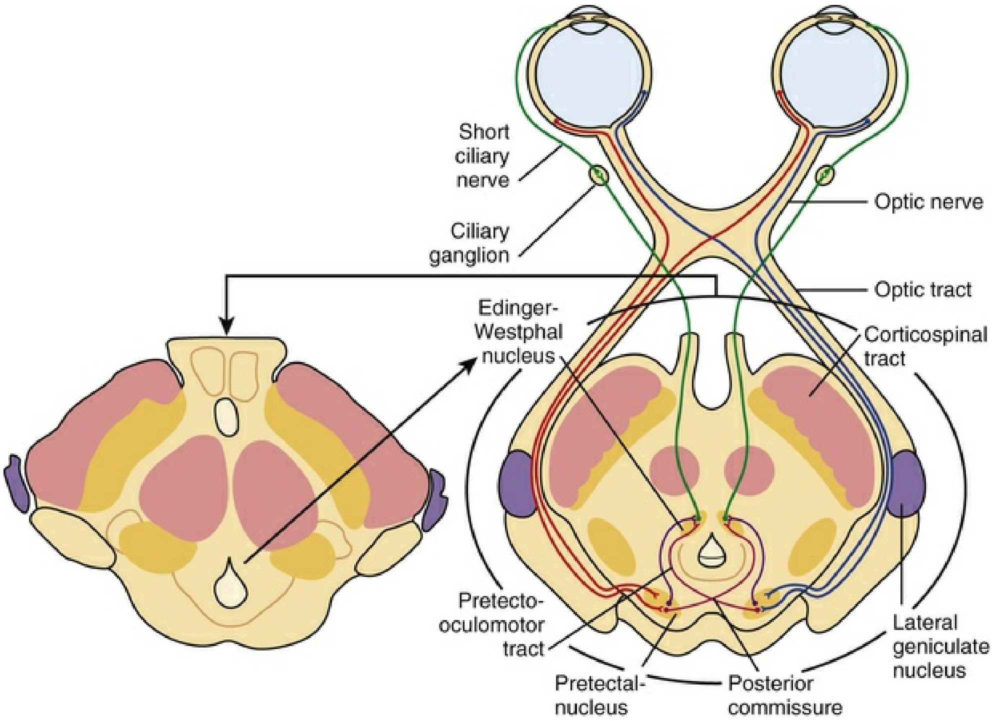

FIG. 65.4 Parasympathetic pathway for pupillary innervations. (Modified from Martin TJ, Corbett JJ. The pupil. In: Krachmer JH, ed. Neuro-ophthalmology: The Requisites in Ophthalmology. St. Louis: Mosby; 2000. Copyright 2000 Elsevier.)

Pupillary dilation is mediated through the three-neuron sympathetic (adrenergic) pathways (Fig. 65.5). Sympathetic fibers originate in the hypothalamus and descend caudally to synapse in the cervical spinal cord between levels C8 and T2 at the area of the ciliospinal center of Budge. Neurons then travel from the cervical spinal synapse through the brachial plexus, over the lung apex, and ascend to the superior cervical ganglion near the angle of the mandible at the bifurcation of the common carotid artery. Postganglionic fibers then ascend within the adventitia of the internal carotid artery through the cavernous sinus in close relation to the sixth cranial nerve. Finally, the oculosympathetic pathway joins the ophthalmic division of the fifth cranial nerve (trigeminal nerve) and innervates the dilator pupillae and Müller muscle (a small smooth muscle in the eyelids responsible for a minor portion of the upper lid elevation and lower lid retraction).

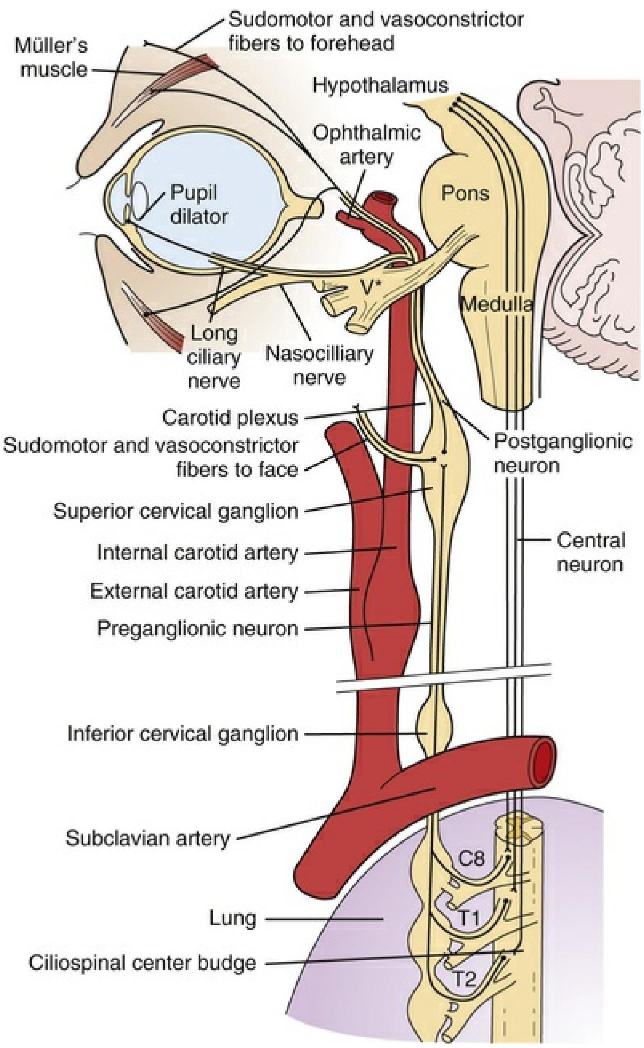

FIG. 65.5 Sympathetic pathway for pupillary innervations. (Modified from Martin TJ, Corbett JJ. The pupil. In: Krachmer JH, ed. Neuro-ophthalmology: The Requisites in Ophthalmology. St. Louis: Mosby; 2000. Copyright 2000 Elsevier.)

Anisocoria is indicative of a lesion in the efferent fibers supplying the pupillary sphincter muscles (dilator pupillae and the sphincter pupillae). Pupillary size is determined by the average amount of illumination detected by each eye. Because the efferent limb of the pupillary reflex is bilateral, both pupils receive the same command and are always the same size. Lesions in the afferent limb of the pupillary reflex do not produce anisocoria if the consensual pupillary response to light is intact. Afferent pupillary defects are noted when the direct and consensual responses to light are different. The examiner will note that the pupil's reaction to direct light is more sluggish, initially slower, or absent. If the afferent defect is severe, the pupil in the affected eye will dilate with direct light. An afferent papillary defect is a sensitive marker for abnormalities of the afferent limb of the visual pathways.

When anisocoria develops, it is important to determine the abnormal pupil (Fig. 65.6). If the small pupil is abnormal, anisocoria is greater in darkness than in light and one will note poor pupillary dilation on the abnormal side. This problem is seen with abnormalities of the sympathetic system. If the larger pupil is abnormal, anisocoria is greater in light than in darkness and one notes poor pupillary

constriction on the abnormal side. Poor pupillary constriction is consistent with an abnormality of the parasympathetic system.

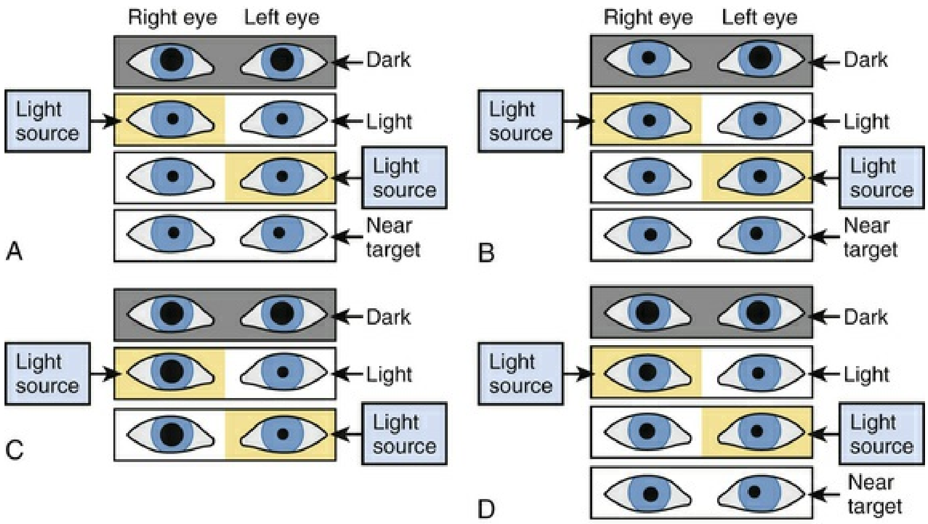

FIG. 65.6 The pupillary examination. Identification of the abnormal pupil when anisocoria is present. (A) Normal pupillary reactions. Both pupils are symmetric in the light and dark. (B) The small pupil is abnormal. The right pupil does not dilate well in the dark. (C) The large pupil is abnormal. The right pupil does not react well to light. (D) Physiologic anisocoria. The amount of anisocoria is the same in light and dark. (Modified from Kedar S, Biousse V, Newman NJ. Approach to the patient with anisocoria. In: Brazis PW, Wilterdink JL, eds. Up to date. Available at www.uptodate.com.)

Third nerve palsy is the result of lesions anywhere between the oculomotor nucleus and the extraocular muscles. The third cranial nerve originates in the region of the superior colliculus in the midbrain. Fibers travel ventrally in the midbrain and pass the red nucleus and the corticospinal tracts. The nerve exits the midbrain and passes along the brain stem and courses along the lateral wall of the cavernous sinus. The third nerve enters the orbit at the superior orbital fissure. In the orbit, parasympathetic fibers join the periphery of the nerve and travel to the ciliary ganglion. The third nerve innervates the levator muscle of the eyelid, four of the six ipsilateral extraocular muscles (the medial rectus, the superior rectus, the inferior rectus, and the inferior oblique), and the sphincter pupillae (parasympathetic fibers). Remaining extraocular muscles, the superior oblique muscle and the lateral rectus muscle, are innervated by fourth and sixth cranial nerves, respectively.

Third nerve palsies present with ptosis, gaze abnormalities, and varying degrees of pupillary dysfunction.[8] Pupillary response will vary with the degree of injury, and pupils may be of normal size with normal responses to light, dilated and poorly reactive to light, or dilated and unresponsive to light and near stimulus. Gaze abnormalities also vary with the site and severity of injury. Adduction abnormality occurs as a result of medial rectus weakness, and the eye is turned out. Injury to the nerve supply of superior rectus or inferior oblique results in elevator muscle weakness, and the eye is turned down. Weak downward gaze results from injury to the nerve supply of the inferior rectus muscle, and the eye is turned up. Classically, third nerve palsy is complete and all muscles are affected, resulting in an eye that is

turned down and out.

Fundi should be examined to assess the presence of papilledema and retinal hemorrhages. Papilledema is a late sign of increased ICP, and its absence does not rule out raised ICP. Signs of papilledema include blurring of the margins of the optic disc and a decrease in venous pulsations. Retinal hemorrhages are most commonly associated with abusive head trauma associated with child abuse, although they may be seen following cardiopulmonary resuscitation or acute intracranial hemorrhage. Hemorrhages in the retina appear as perivascular collections of blood that may coalesce to include large areas of the retina. Retinal hemorrhages appear to be associated primarily with significant head injury that disrupts retinal blood vessels between the internal limiting membrane and the ganglion cell layer and vessels in the nerve fiber layer of the retina.

The oculocephalic or so-called doll's eye reflex and the oculovestibular or caloric reflex are the two specific eye maneuvers used in evaluating the comatose child. A positive or normal response to these reflexes indicates that much of the brain stem is intact. Conjugate deviation is noted toward the side of cerebral lesions and away from the side of brain stem lesions. The corneal reflex is a good test for mid- and low-pontine function.

Motor Examination

Motor examination may reveal focal or generalized neurologic deficits. The presence or absence of focal lateralizing neurologic signs sharply shortens the differential diagnosis. If a single anatomic lesion can explain all the signs, then the differential diagnosis shortens to structural CNS causes of coma. If there is neuroanatomic inconsistency, toxic and metabolic causes of coma are most common (Table 65.4). It is important to remember that focal dysfunction may be misinterpreted as altered LOC (eg, a patient with receptive aphasia who is misdiagnosed as confused or psychotic).

TABLE 65.4

Clinical Findings With Different Levels of Central Nervous System Dysfunction

Dysfunction	Response to Noxious Stimuli	Pupils	Eye Position and Movements	Breathing	Motor Findings for Structural Lesions
Both cortices	Withdrawal	Small, reactive	Extraocular movements can be elicited; ipsilateral deviation in frontal lobe lesion	Posthyperventilation apnea or Cheyne-Stokes respiration	Contralateral hemiparesis
Thalamus	Decorticate posturing	Equal and small, unless the optic tract is also damaged	Eyes deviated down and in toward the side of lesion	Same as above	Contralateral hemiparesis
Midbrain	Decorticate or decerebrate posturing	Midposition, fixed to light, spontaneous fluctuation	Nystagmus may be present; absent vertical but retained horizontal movements; loss of ability to adduct both eyes may be deviated laterally and down in third cranial nerve damage	Usually same as above; potential for central reflex hyperpnea	Hemiplegia with contralateral third cranial nerve palsy
Pons	Decerebrate posturing	Bilateral pinpoint pupils, reactive to light (especially with midline pontine hemorrhage); Horner	Ocular bobbing; absent conjugate horizontal movements with retained vertical movements and accommodation; often eyes are	May exhibit central reflex hyperpnea, cluster (Biot) breathing, or apneustic breathing	Hemiplegia with contralateral sixth or seventh

		syndrome with lateral lesions	deviated medially; seventh cranial nerve damage		cranial nerve palsy
Medulla	Weak leg flexion (or none)	Nonreactive, normal size; small, Horner syndrome with lateral lesions	Usually no effect on spontaneous eye movements; may interfere with reflex responses, nystagmus	Rarely ataxic respiration, apnea if respiratory centers involved	Flaccid weakness with difficulty swallowing, phonating, and incoordination
Spinal cord	None	Normal reaction, abnormal response if brain stem affected	Normal response	Normal	Flaccid weakness, loss of bowel and bladder control

Fig. 65.7 describes the path of the corticospinal tracts through the midbrain, pons, and medulla and their relationship to cranial nerve nuclei. The anatomic relationships between the cranial nerves and motor tracts can provide clues to the location of lesions when a careful physical examination is performed. Physical examination findings and their expected anatomic correlates are presented in Table 65.3.

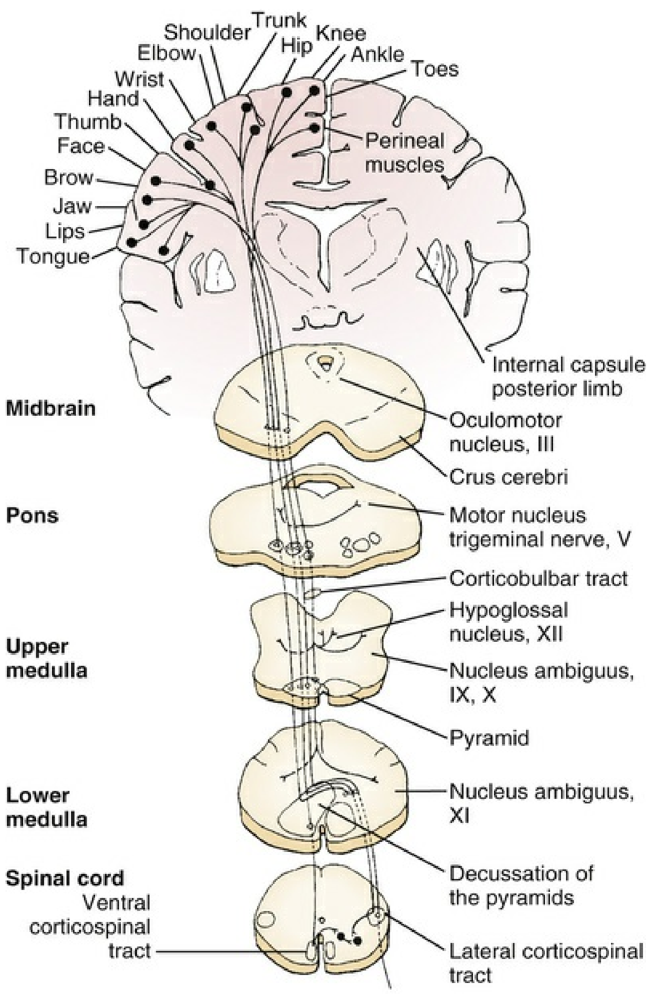

FIG. 65.7 The corticospinal tracts in relation to the cranial nerve nuclei. (Modified from Gilman S, Newman SW. Manter and Gatz's Essentials of Clinical Neuroanatomy and Neurophysiology. 9th ed. Philadelphia: FA Davis; 2003.)

Focal Neurologic Lesions Could Be Supratentorial or Subtentorial

The *supratentorial* compartment mainly contains the cortex, thalamus, and other structures above the midbrain (Figs. 65.8 and 65.9). Patients presenting with asymmetrical examinations are indicative of those with cortical lesions. Given a "focal" or asymmetrical examination, hemiparesis suggests a lesion in a contralateral upper motor neuron pathway. Hypotonia, diminished LOC, and equal reactive pupils are likely to be localized to a cortical lesion on the contralateral side. It has been noted, however, that unilateral cortical lesions often dampen alertness but do not lead to stupor or coma, because ARAS is widely spread in the cerebral cortex region. Expansion of cortical lesions resulting in raised ICP may reduce cortical blood flow in the other areas of the brain, causing diminished LOC.

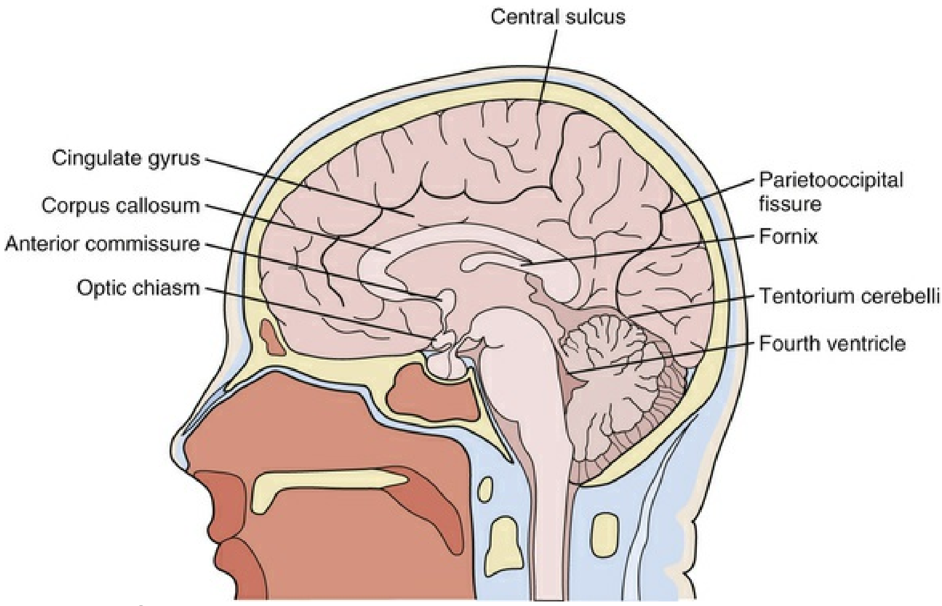

FIG. 65.8 Supratentorial and subtentorial compartments. (Modified from Gilman S, Newman SW. Manter and Gatz's essentials of clinical neuroanatomy and neurophysiology. 9th ed. Philadelphia: FA Davis, 2003.)

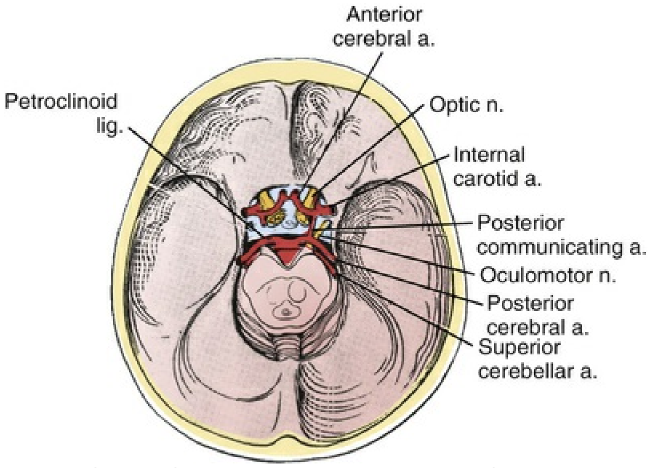

FIG. 65.9 The floor of the anterior and middle fossa, illustrating the tentorial notch and relationship of the third nerve with other intracranial structures. (Modified from Plum F, Posner JB. The Diagnosis of Stupor and Coma. 3rd ed. Philadelphia: FA Davis; 1982.)

Contralateral thalamic lesions and cortical lesions with a retrocaudal progression present with contralateral hemiparesis, decorticate (flexor) posturing, eyes deviated inferiorly and medially, and pupils remaining equal, small, and reactive. Flexor (decorticate) posturing (ie, tonic flexion of upper extremities and tonic extension, adduction, and internal rotation of lower extremities) reflects a lesion above the midbrain as described in Fig. 65.10.

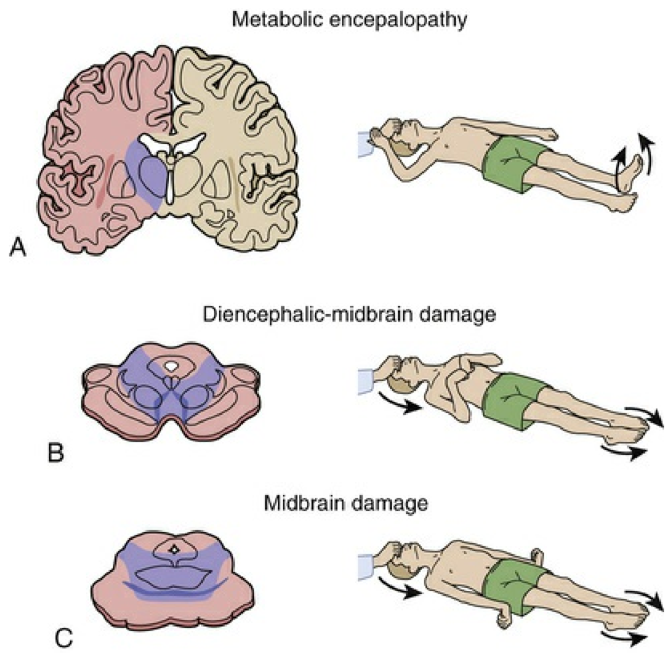

FIG. 65.10 Motor responses to noxious stimulation in patients with cerebral dysfunction. (Modified from Posner JB, Saper CB, Schiff ND, et al., eds. The Diagnosis of Stupor and Coma. 4th ed. New York: Oxford University Press; 2007.)

The history and physical findings are relevant and may help determine the cause of the injury. A sudden change in LOC in an otherwise normal child may be due to a cerebrovascular accident from an arteriovenous malformation, a bleeding CNS

tumor, or a ruptured aneurysm. Acute sinusitis may result in intracerebral or subdural empyema resulting from either direct extension or hematogenous spread of infection. These infections may produce diminished LOC either as a result of the systemic inflammatory response to the infection or as a consequence of the expanding mass lesion. A history of fever associated with a diminished LOC may suggest encephalitis associated with herpes simplex or arboviruses infections (see also Chapter 70).

A murmur, gallop, or dysrhythmias detected during a cardiovascular examination may suggest congenital heart disease or endocarditis, which may be associated with stroke or intracranial abscess formation. Generalized petechia and purpura may be seen with thrombocytopenic purpura, which is a risk factor for spontaneous intracranial bleeding.

When a traumatic injury occurs, coma may exist from the moment of impact or may be preceded by a lucid interval, suggesting an expanding epidural hematoma. A complete description of TBI is provided in Chapter 119.

Patients presenting with an altered level of consciousness and underlying illnesses such as systemic lupus erythematosus, sickle cell anemia, nephrotic syndrome, homocystinuria, leukemia, or coagulation disorders such as protein C and S deficiency are at risk for cerebral infarction resulting from a vascular obstruction. Patients with diabetic ketoacidosis may have a sudden onset of coma that could be a result of cerebral edema or central venous thrombus (see also Chapter 86). Hypoxic insults and penetrating injuries to vertebral or carotid arteries (as a consequence of vascular disruption) can result in cerebral infarction. Patients with strokes may have a period of lucidity following the acute vascular incident. Stupor and coma develop as swelling increases ICP and the blood supply to the midbrain and brain stem are compromised.

Vomiting and diarrhea leading to severe dehydration and hypercoagulable states may lead to sinus venous thrombosis, particularly in infants. Orbital cellulitis can result in cavernous venous thrombosis. Children with congenital heart disease, especially with right-to-left shunts, are susceptible to cerebral embolism resulting from blood or air thrombus or particles when patients are treated with intravenous therapy.

Diminished LOC also may occur because of bleeding, convulsions, or rapidly rising ICP as a result of a brain tumor. A history of headache may suggest elevated ICP resulting from hydrocephalus or neoplasm but also may be seen in migraine syndrome with impaired consciousness. The presence of neurocutaneous lesions, such as depigmented areas of tuberous sclerosis, can suggest that seizures or intracranial masses are the cause of diminished LOC.

The *subtentorial* compartment is the area beneath the tentorium and contains most of the brain stem, the cerebellum, the exit sites for most of the cranial nerves, and passages for cerebrospinal fluid (CSF) flow (see Figs. 65.8 and 65.9). Injury and insult can alter function of these components by either destruction or compression. Brain stem lesions are capable of creating immediate LOC because of the close proximity of ARAS. The relationship of cranial nerves to the brain stem is described in Fig. 65.11.

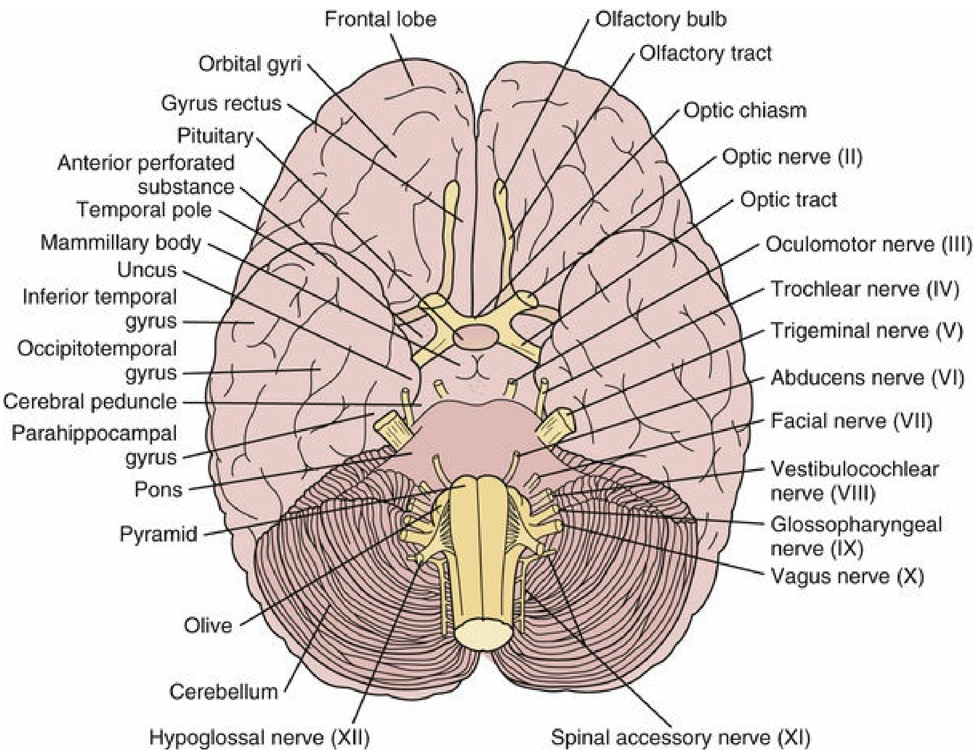

FIG. 65.11 Ventral surface of the brain demonstrating the position of cranial nerves. (Modified from Gilman S, Newman SW. Manter and Gatz's Essentials of Clinical Neuroanatomy and Neurophysiology, 9th ed. Philadelphia: FA Davis; 2003.)

Lesions in the brain stem may be due to demyelinating diseases, cerebrovascular diseases, neoplasm, or head trauma. Uncal herniation can occur following head trauma, which may be due to rapidly expanding subdural or epidural hematoma or diffuse axonal injury. A history of fever, vomiting, and LOC is noted in brain stem and cerebellar infarction. Cerebrovascular lesions disrupt blood supply and result in brain stem dysfunction. A history of headache, vomiting, and gait unsteadiness may suggest a neoplasm.

Midbrain lesions frequently present with ipsilateral weakness and a midposition, nonreactive contralateral pupil due to third cranial nerve palsy. Third cranial nerve palsy generally causes both eyes to deviate laterally or inferiorly and laterally. When gaze is deviated down and out, the patient is said to have the “sun setting sign.” Extensor (decerebrate) posturing is elicited in response to noxious stimuli in patients with midbrain lesions. Extensor posturing is the tonic extension of upper extremities as well tonic extension, adduction, and internal rotation of lower extremities (see Fig. 65.10).

Hemiparesis and medial deviation of the contralateral eye are hallmarks of pontine lesions (see Fig. 65.3). Pupils remain small and reactive to light. However, bilateral pinpoint pupils are also seen when midline pontine hemorrhages occur. Horner syndrome with a mildly constricted pupil ipsilateral to the lesion can be seen in lesions affecting pathways between the hypothalamus and brain stem.

Although hypertonia is a feature of preexisting corticospinal tract injury, it can be seen in acute injury to the midbrain or pons, when the more rostral corticospinal tract is disrupted, but the vestibulospinal motor system continues to exert a tonic influence on the spinal cord. These patients exhibit extensor (decerebrate) posturing to noxious stimuli. It should be noted that acute lesions often cause extensor

posturing regardless of anatomic location, and both flexion and extensor posturing may occur in combination. These facts render posturing less reliable for localization of CNS lesions. Although not always reliable for localization, posturing suggests that cortical control centers are not functioning.

Patients presenting with flaccid quadriplegia, swallowing difficulties, problems with phonation, nonreactive normal-sized pupils, and normal extraocular eye movements are likely to have an injury in the medulla. The eighth to twelfth cranial nerves exit the brain stem in the area of the medulla. Medullary lesions are associated with problems in bulbar muscles such as speech and swallowing. If respiratory centers are affected, patients may present with apnea. Cerebellar lesions usually produce coma by brain stem compression. Cerebellar signs in confused patients should raise the possibility of intoxication or nutritional deficiency (eg, vitamin B_{12}).

Presentation of Nonfocal Neurologic Lesions

Once causes of focal neurologic lesions have been excluded, further evaluation should proceed to seek causes of coma as described in Box E65.1. Patients with nonfocal lesions and coma commonly lie motionless in an unnatural posture. In most metabolic conditions, pupils are small and reactive to light and extraocular movements are absent. Patients may hyperventilate or present with apnea or Cheyne-Stokes respiration.

Hypoxia and ischemia/reperfusion injury are important causes of coma in pediatric patients. These entities are thoroughly discussed in Chapter 68. Most of the causes of nonfocal neurologic lesions may be obvious. In cases of unusual presentation, a detailed history and physical examination may give a clue to the diagnosis.

Coma preceded by sleepiness or unsteadiness suggests ingestion of a drug or toxin in a previously healthy child. Seizures may lead to a prolonged and deep loss of consciousness if there is an underlying reason for the seizure (eg, cerebral palsy, hypoglycemia, and electrolyte abnormalities) or if metabolic demand during the seizure is not met by a concomitant increase in substrate delivery. A recent history of fever or upper respiratory tract illness may suggest complications of infectious diseases such as acute disseminated encephalomyelitis, Reye syndrome, or mitochondrial disorders.

Intermittent episodes of coma may be due to recurrent drug overdose, inborn error of metabolism, or Munchausen syndrome by proxy. A toddler presenting with intermittent irritability followed by a decreased level of consciousness could be experiencing intussusception.

Inspection of the patient's skin can provide clues to an underlying illness (eg, jaundice in patients with liver failure or a cherry-red color in persons with carbon monoxide poisoning). Generalized increased pigmentation may be seen in cases of Addison disease or adrenoleukodystrophy.

Herniation Syndromes

Expanding mass lesions develop at the expense of one of the CNS compartments

(brain, blood, or CSF). Herniation occurs when the brain is subjected to pressure gradients that cause portions of it to flow from one intracranial compartment to another. Although the brain has substantial elasticity, the arteries and veins responsible for its blood supply are relatively fixed in space, creating a risk that brain shifts will cause moving portions to lose their blood supply. The supratentorial compartment is connected to the subtentorial compartment via the tentorium cerebelli, which passes through the tentorial notch (see Fig. 65.9). Located in the tentorial notch are the midbrain, the third cranial nerve, and several arteries including choroidal arteries, the posterior cerebral arteries, and the superior cerebellar arteries. The cerebellum occupies the posterior part of notch. Close proximity of these important structures explains the constellation of symptoms that occurs when supratentorial lesions lead to transtentorial shifts.

Two herniation syndromes are principally important: central herniation and uncal herniation (Fig. 65.12). *Central herniation* occurs when diffuse brain swelling or a centrally located mass causes the diencephalon to move caudally through the tentorial notch. Dysfunction of the ARAS and cerebral hypoperfusion cause the alteration of consciousness. Patients initially become less alert and later progress to stupor and coma. Diencephalic dysfunction initially produces small reactive pupils because sympathetic output from the hypothalamus is lost. At this stage, flexor (decorticate) posturing may be spontaneous or elicited by noxious stimuli, and Cheyne-Stokes respiration is noted (see Fig. 65.2). It is important to recognize this constellation of symptoms because herniation at this stage is reversible. As rostral-caudal progression of central herniation continues into the midbrain and pons, the likelihood of reversibility markedly decreases. As the midbrain begins to fail, pupils enlarge to midposition, and decerebrate (extensor) posturing is noted. Attempts to elicit horizontal eye movements with either cerebroocular reflex or cerebrovestibular reflex fail, and the respiratory rhythm becomes irregular. The patient becomes overtly comatose. Further progression affects the medullary respiratory centers. Virtually all brain stem reflexes are absent and death becomes imminent. The initial cardiovascular response to diminished brain stem perfusion is hypertension, which leads to reflex bradycardia. Classic Cushingoid reflex responses are seen mostly after the development of herniation syndromes. Radiographically, downward herniation is characterized by obliteration of the suprasellar cistern from temporal lobe herniation into the tentorial hiatus with associated compression on the cerebral peduncles.

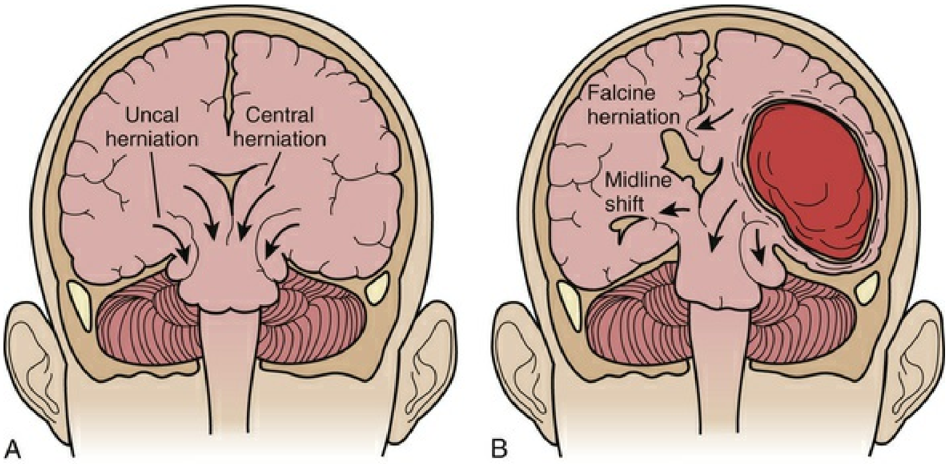

FIG. 65.12 Central (A) and uncal (B) herniation. (Adapted from Posner JB, Saper CB, Schiff ND, et al., eds. The Diagnosis of Stupor and Coma. 4th ed. New York: Oxford University Press; 2007.)

Uncal herniation occurs when a lateral expanding cerebral mass pushes the uncus and hippocampal gyrus over the lateral edges of the tentorium, putting pressure on the brain stem, especially the midbrain. As the diencephalons begin to shift away from the mass, consciousness begins to diminish, and ipsilateral third cranial nerve palsy develops. When the third cranial nerve is compressed against the tentorial notch, the pupillary fibers controlling the parasympathetic control are primarily damaged, resulting in a large pupil of the affected side, which fails to constrict to the light. A unilateral dilated pupil that is first to appear, often without severe impairment of consciousness, and contralateral hemiparesis are the hallmark findings of uncal herniation. Other findings, such as impaired ocular motility pushing an eye “down and out,” may take some time to develop. Cranial arteries may be compressed during herniation. Once present, changes in brain stem function, ipsilateral hemiplegia, and altered oculocephalic reflexes may proceed rapidly. In some patients bilateral pupillary dilatation develops, presumably because of distortion of third cranial nerve anatomy and midbrain ischemia. At this point, uncal herniation begins to affect the midbrain and upper pons, producing fixed pupils and extensor posturing, lethargy, bradycardia, and respiratory abnormalities. Further progression is indistinguishable from central herniation.

Cerebellar tonsillar herniation is seen in patients with posterior fossa masses that cause compression of the brain stem, cranial nerve dysfunction, and obstructive hydrocephalus. As the pressure gradient across the foramen magnum increases, cerebellar tonsils may be pushed through the foramen and also can compress the upper cervical spinal cord. Increased pressure on the brain stem can result in dysfunction of brain centers responsible for controlling respiratory (and cardiac) function, which may result in apnea. Patients with cerebellar tonsillar herniation may complain of neck pain before losing consciousness. *Upward transtentorial herniation* occurs when contents of the posterior fossa herniate into the diencephalic region. This syndrome can be seen in patients who have ventricular drains placed for relief of hydrocephalus or with posterior fossa mass lesions. If a low to high pressure differential is created between the supratentorial and subtentorial regions, respectively, upward transtentorial herniation may occur.

Diagnostic Evaluation

Initial investigation falls into two broad categories: investigation facilitating supportive therapy during the child's illness and investigation to confirm a specific diagnosis (Box E65.2). These investigations, however, should be tailored to the individual child's history and physical examination. Blood chemistry profile should include glucose, sodium, potassium, blood urea nitrogen, calcium, magnesium, carbon dioxide (CO_2), and ammonia. Hypoglycemia may be a presenting feature of some endocrine disorders or inborn errors of metabolism (see also Chapter 82). Therefore all patients with significant impairment of consciousness should have a blood glucose determination performed immediately after presentation. Abnormalities of calcium and magnesium may precipitate unexpected seizures, especially in infants and young children. Hyperammonemia and metabolic acidemia may occur as a result of an inborn error of metabolism. If metabolic acidosis is noted, then lactate and pyruvate levels also should be determined. A complete blood cell count will assist in determining the presence of infection, anemia, and exposure to toxins such as lead. Blood and urine cultures should be obtained if infection is suspected. A urine sample also should be sent for toxicology screening.

Box E65.2

Diagnostic Evaluation in a Patient With Coma

Electronic Supplement

Investigations That Facilitate Supportive Therapy

Arterial blood gas level

Urea, electrolytes and creatinine, calcium, and magnesium levels

Blood sugar level

Osmolality of plasma and urine

Urine for ketones, sugar, and pH measurements

Complete blood cell count

Coagulation screening

Blood culture, urine culture, tracheal culture

Blood levels of anticonvulsants

Virology

Chest radiograph

Electrocardiogram

Electroencephalogram

Cerebral imaging: CT, MRI

Brain stem auditory-, visual-, and somatosensory-evoked potentials

Tests That May Provide a Specific Diagnosis

CSF examination

Toxicology screen

Blood ammonia level

Blood pyruvate and lactate levels

Amino acid profile

Organic acid analysis

Porphyrin levels

Liver function tests

Carnitine level

Serum lead level

Cortisol level

Skeletal survey

Cerebral imaging

Though exposure to radiation should be judicious, computerized tomography (CT) remains a valuable imaging tool for evaluating patients presenting with impaired consciousness. Frequently, magnetic resonance imaging (MRI) will be used as the first imaging modality in patients presenting with impaired consciousness as it offers a more sensitive evaluation without exposure to radiation. Once stable, most patients with impaired consciousness of undetermined etiology should undergo neuroimaging for structural causes of pathology (eg, trauma, tumor, bleeding, infarction, abscess, or calcifications). MRI also is valuable for identifying sinus thrombosis, herpes simplex encephalitis, or acute demyelinating process (see also Chapter 63). Lumbar puncture should be deferred until the patient is neurologically and hemodynamically stable and the possibility of raised ICP is eliminated. A normal CT scan is not a definitive indication of normal ICP; however, it can provide evidence in support of the physical examination. CSF should be collected to rule out bacterial infection as soon as it is deemed safe. Freezing a portion of the sample may assist in identifying viral or metabolic causes later. Additional blood or urine samples also may be obtained for further studies at later stages depending on the

patient's clinical course and the initial laboratory evaluation. The electroencephalogram (EEG) is essential to confirm clinically apparent or diagnose subclinical seizures; it also is helpful in determining the prognosis in patients with hypoxic-ischemic encephalopathy (HIE) and in the diagnosis of brain death (see also Chapters 67 and 68).[9]

Therapeutic Intervention

Pathophysiology following brain injury occurs in two phases: primary and secondary. Primary brain injury refers to the initial insult, whether it is ischemic, anoxic/hypoxic, excitotoxic, or shear injury, each potentially resulting in irreversible neuronal cell injury or death. The only available treatment is prevention. Secondary brain injury occurs in otherwise salvageable brain tissue as a result of cerebral hypoxia, hypoperfusion, intracranial hypertension, prolonged excitotoxicity, oxidative stress, or inflammation and may result in further neuronal damage. The goal of therapy is to prevent secondary brain injury.

In neurologic emergencies, evaluation of the patient's airway patency, ventilation, and circulatory status is paramount. Compared with other organs, metabolic activity in the brain is relatively high. The brain has little capacity to store glucose and accordingly depends on constant delivery of substrate and oxygen to maintain normal metabolic functions. Comatose patients often are hypercapnic and have hypoxemia. Thus supplemental oxygen should be provided to the patient with hypoxemia during the initial evaluation.

Upper airway obstruction as a result of decreased muscle tone of the pharyngeal soft tissue is a common problem in unresponsive patients. Once the cervical spine is protected, the clinician should always be prepared to support the airway with maneuvers that improve patency or with endotracheal intubation in unstable patients and in patients likely to become unstable. Once the patient's airway is maintained, adequacy of ventilation must be evaluated by examining the respiratory rate and respiratory effort. It also is common practice to endotracheally intubate patients with a GCS score less than 8, hemodynamic instability, or neurologic instability. In most circumstances, it is safer to endotracheally intubate electively rather than emergently to protect an already compromised brain from further injury as a result of respiratory failure. During endotracheal intubation, special precautions should be taken to protect cerebral circulation and prevent further increases in ICP. Pretreatment with lidocaine and thiopental may help to diminish raised ICP associated with airway manipulation. It is also important to maintain $Pa\text{CO}_2$ between 35 and 40 mm Hg.

Following stabilization of the airway and breathing, hypotension must be corrected to reestablish adequate cerebral blood flow and hence oxygen and substrate delivery. Once hypotension is corrected, some evidence indicates that blood pressure should be maintained higher than the 50th percentile for age to maintain adequate cerebral perfusion pressure pending placement of ICP monitoring equipment. Current guidelines suggest that isotonic solutions without dextrose are the preferred fluid for traumatic or ischemic CNS resuscitation in the absence of hypoglycemia.[10] However, any level of hypoglycemia must be avoided (see the next section).

Immediately Treatable Forms of Coma

After initial stabilization, clinicians should rapidly consider the causes of unresponsiveness that could easily and quickly be reversed. Experience gained from unresponsive adults suggests that all unresponsive infants and children should be immediately checked for hypoglycemia. Infants are susceptible to hypoglycemia because of immature glycogen storage and a higher metabolic rate. The blood glucose level can be checked quickly with use of a glucose reagent strip, and abnormalities can be treated immediately with a bolus of dextrose.

An overdose of narcotics should be considered in older children and adolescents. Particularly if the history and physical findings suggest narcotic ingestion, a trial of naloxone is warranted.

Seizures should always be considered, especially when the cause of coma is undetermined. Seizures should be treated immediately because a prolonged status epilepticus has a high mortality rate and has been shown to cause neuronal necrosis. An extensive discussion of seizures and their treatment is provided in Chapter 67.

Rapidly Progressive Reversible Lesions

Space-occupying lesions frequently result in increased ICP, and this situation must be addressed immediately to avoid further damage and death. Therapy must be directed toward limiting the extent of secondary damage and preventing herniation by reducing ICP or surgically addressing the lesion or hydrocephalus if present. When signs of central or uncal herniation are noted, the physician must respond rapidly and attempt to decrease ICP by altering the volume of one of the three intracranial constituents: brain, blood, or CSF. Interventions include elevating the head of bed 30 degrees, keeping the head in midline position, hyperventilation, and administration of mannitol or hypertonic saline solution to rapidly decrease intracranial volume and ICP.[10] A complete discussion of treatment of ICP is presented in Chapter 66.

States Amenable to Prolonged Therapy

Certain brain insults are not readily reversible and require prolonged treatment to obtain the best possible outcome. Although the primary insult may not be reversible or may require extended care, secondary injury such as hypoxia and raised ICP can occur and cause further deterioration, despite the fact that the initial injury may not progress. Examples of primary insults that can have major secondary changes include encephalitis, meningitis, hypoxic-ischemic insults, and certain metabolic abnormalities such as hepatic failure and renal failure. Thus broad-spectrum antibiotics and antiviral therapy should be empirically started when meningitis or encephalitis is suspected, even if the lumbar puncture is deferred. Electrolyte imbalance, especially related to serum sodium either as an underlying cause or as a result of CNS insult due to inappropriate antidiuretic hormone secretion or diabetes insipidus, also should be appropriately corrected. It may be preferable to target high-normal serum sodium levels (~145 mEq/L) if possible for the first 72 hours if intracranial hypertension is confirmed or suspected. Hypoglycemia or hyperglycemia and variation in glucose level are associated with increased morbidity and mortality[11] and should be monitored and prevented, and

hypoglycemia should be immediately treated. Adequate blood pressure to maintain cerebral perfusion pressure is immensely important and should be achieved with appropriate fluid resuscitation or inotropic support if necessary. Untreated hypotension in patients with TBI is associated with increased morbidity and mortality. Although therapeutic hypothermia for the initial 24 to 48 hours following anoxia-ischemia has been shown to be beneficial in newborns and adults following ventricular tachycardia/fibrillation cardiac arrest,[12] its utility in children is not established (see Chapter 68). Moreover, data suggest that prevention of fever via targeted temperature management (therapeutic normothermia) may be as efficacious after cardiac arrest in adults. Agitated patients may require sedation to prevent elevations in ICP. Patients should be adequately sedated for comfort and prevention of complications related to ventilation. Analgesia/anxiolysis titration using a standard scoring system can be helpful. Patients at risk of or demonstrating overt or subclinical seizures should be treated appropriately.

Outcome

The major causes of pediatric coma involve HIE and trauma. These conditions are serious and are common reasons for admission to the pediatric intensive care unit. Coma is associated with high morbidity and mortality. It also is hard to predict outcome early in the course. In children, improvement can continue over a very protracted time, even several years, long beyond the time when most adult patients will have reached their plateau of recovery.[13] Thus it is important to provide accurate and timely prognostic information if possible so that appropriate levels of care can be provided. The combination of physical signs, EEG, evoked potentials, and MRI provides useful prognostic information after 24 hours of HIE and can help in predicting outcome. These tests may need to be delayed to rule out compounding factors, or multiple tests may be required to provide the best prognostic information to families.[9]

TBI is a leading cause of death and disability in the pediatric age group. Neuropsychologic and behavioral outcomes depend not only on the severity and type of injury and age at injury but also on premorbid conditions and the families' socioeconomic status.[14-16] Hypotension alone and hypoxemia associated with hypotension are significant predictors of disability and death in patients admitted with moderate to severe TBI. Early fluid resuscitation for hypotension, oxygen supplementation for hypoxemia, and ventilation for apnea in patients with TBI can have a significant impact on outcome. Also, the presence of vascular injury, refractory ICP, elevated ICP, and cisternal effacement at presentation had the highest correlation with subsequent mortality and morbidity. Controlling elevated ICP is an important factor associated with survival following severe pediatric TBI.[17]

The outcome of coma following cardiopulmonary arrest is associated with greater than 80% mortality. Patients with out-of-hospital arrests have a worse outcome than those with in-hospital arrests. Factors associated with mortality were duration of asystole more than 15 minutes and administration of more than one dose of epinephrine.[12] Patients who were alert before resuscitation had better survival beyond 24 hours than did those who were comatose (see Chapter 68).

The precise prognosis of children with severe submersion injuries is difficult to determine within the first few hours of injury. In general, prolonged

cardiopulmonary resuscitation, fixed and dilated pupils, and a GCS score of 3 portend a poor outcome (see also Chapter 116).[18,19] Orlowski[19] developed a scoring system for evaluating prognosis in submersion injury based on five unfavorable prognostic factors: age less than 3 years, estimated submersion longer than 5 minutes, no attempts at resuscitation for 10 minutes, coma on admission to the emergency department, and severe acidosis with arterial blood pH 7.1 or less. A total score of 2 or less was associated with 90% chance of recovery, but a score of 3 or greater was associated with only a 5% chance of recovery.[19] Coma following cerebral edema in patients with diabetic ketoacidosis is unpredictable, and outcomes vary and may not be related to any specific management strategy.[20]

Ethical Considerations

The main purpose of coma prognostication is not merely to satisfy a parent's anxiety to know what the future holds but primarily to assist with difficult management decisions. If there is a high probability of death without regaining consciousness, decisions to withdraw life-sustaining technologies often are made. By contrast, a decision to withdraw support based on a high probability of survival with severe motor or mental disability is ultimately a judgment about quality of life, with the implication that “life with severe disability is worse than no life at all.” Currently it is not possible to precisely predict outcome in patients in persistent vegetative or minimally conscious states,[21] as distinct from death on the one hand or severe disability on the other. Life and death judgments based on quality of life appear more complex in pediatric versus adult patients.

Terms such as *mild, moderate,* or *severe* disability can subjectively describe levels of neurologic dysfunction. Categories such as *favorable* or *unfavorable* convey value judgments. Thus it is important to use appropriate terminology for coma prognosis. Parents of disabled children tend to strongly disagree with subjective and judgmental terminology, such as life with a *poor* or *unfavorable* outcome. Thus with respect to ethical implications as well as the neurobiology of coma prognosis, the adage holds true: “Children are not miniature adults.”

CHAPTER 66

Intracranial Hypertension and Brain Monitoring

Robert C. Tasker, Marek Czosnyka

PEARLS

- As intracranial hypertension progresses, changes may occur in the vital signs, with an elevation of blood pressure, a decrease or an increase in pulse, and irregularity in the respiratory rhythm. These signs, sometimes associated with episodes of decerebrate rigidity, indicate the occurrence of transtentorial herniation or "coning" and imply the possibility of impending death if the process cannot be reversed.
- The continuous measurement of intracranial pressure is an essential modality in most brain monitoring systems. After years of enthusiastic attempts to introduce newer modalities for brain monitoring (eg, tissue oxygenation, microdialysis, cortical blood flow, transcranial Doppler ultrasonography, jugular bulb oxygen saturation, and near infrared spectroscopy), the measurement of intracranial pressure remains a robust and only moderately invasive modality, and it can be realistically conducted in most pediatric critical care units.

In most organs in the human body, the environmental pressure for blood perfusion is either low or coupled to atmospheric pressure. The environmental pressure for the brain differs in this respect because the brain is surrounded and protected by a stiff skull. Thus a rise in environmental pressure—intracranial pressure (ICP)—may impede cerebral blood flow (CBF) and cause ischemia. In pediatric critical care, ICP may be of acute significance in a number of instances (eg, traumatic brain injury [TBI], bacterial meningitis, hydrocephalus, and the Fontan circulation). This chapter discusses how information from ICP monitoring and its integration with other forms of monitoring inform the understanding and treatment of brain disorders.

Clinical Background

In critical illness, the early recognition and treatment of intracranial hypertension are

important because it is a major cause of mortality and morbidity. Therefore an attempt should be made to collate the clinical evidence for and against its presence. The early symptoms and signs of this complication, however, which are invariably subtle and nonspecific (Table 66.1), make this form of assessment somewhat limited. As will be discussed later, as intracranial hypertension progresses, changes may occur in the vital signs, with an elevation of systemic arterial blood pressure (ABP), a decrease or an increase in pulse, and irregularity in the respiratory rhythm. These signs, sometimes associated with episodes of decerebrate rigidity, indicate the occurrence of transtentorial herniation or "coning" and imply the possibility of impending death if the process cannot be reversed. Unfortunately, recognition at this stage is often too late to prevent death.

TABLE 66.1

Early, Subtle Symptoms and Signs of Raised Intracranial Pressure

	Infant	Child
General state	Poor feeding	Anorexia and nausea
	Vomiting	Vomiting
	Irritability to coma	Lethargy to coma
	Seizures	Seizures
Head/eyes	Full fontanelle	False localizing signs
	Scalp vein distention	
	False localizing signs	
Other	Altered vital signs	Altered vital signs
	Hypertension	Hypertension
	Pulmonary edema	Pulmonary edema

Brain tissue shifts may produce various "syndromes." First, transtentorial or cerebellar herniation may result in midbrain or medullary compression. Many of the clinical signs observed in association with herniation result from direct compression of structures by the impacted tissue or are due to angulation of nerves or arteries against normal structures in the area. These herniations can cause increasingly dense coma, with distortion of the brain stem leading to midbrain and pontine hemorrhages. Cerebellar herniation is likely to occur when the increase in ICP is maximal in the posterior fossa. Such herniation occurs more commonly downward, squeezing one or more of the cerebellar tonsils through the foramen magnum; compressing the medulla; and leading to neck stiffness, head tilt, lower cranial nerve palsies, respiratory irregularities, or sudden cardiorespiratory arrest. Cerebellar herniation may occur upward through the tentorial notch, causing midbrain compression and leading to paralysis of upward gaze, dilated and fixed pupils, and respiratory abnormalities, although this type of cerebellar herniation is uncommon.

When intracranial hypertension is more marked in the supratentorial compartment, for instance, with acute intracerebral hematoma, the temporal lobe on the affected side may be displaced into the tentorial notch and result in unilateral transtentorial herniation. The herniation may be more marked anteriorly (uncal) or posteriorly (hippocampal) and is usually accompanied by displacement of the ipsilateral cingulate gyrus under the falx (cingulate herniation). Clinical manifestations of this condition may include ipsilateral third nerve palsy, contralateral hemiparesis, respiratory irregularities, deepening coma with decerebrate posturing, and ultimately cardiorespiratory arrest.

Finally, when bilateral or a general increase in ICP in the supratentorial

compartment occurs, as in diffuse cerebral edema, central transtentorial herniation may occur. This condition leads to impairment of upward gaze, pupillary constriction, hypertonus, and decerebrate posturing. Temperature irregularities and diabetes insipidus may develop, and cardiorespiratory arrest may occur eventually. The clinical features of "central syndrome" are summarized in Tables 66.2 and 66.3.

TABLE 66.2

Clinical Features of Central Syndrome or Rostrocaudal Deterioration

Stage	Level of Consciousness	Respiration	Pupil Size and Reactivity	Oculocephalic and Oculovestibular Responses	Posture and Tone
Diencephalic (early to late) ↓	Agitation Drowsiness Stupor	Deep sighs or yawns Occasional pauses Cheyne-stokes or periodic breathing	Small (1-3 mm) with brisk reaction to light	Conjugate at rest and respond quickly	Normal or slightly increased Generalized muscular hypertonus
Midbrain to upper pontine ↓	Coma	Central hyperventilation	Midpositon (3-5 mm) with sluggish reaction to light	Dysconjugate	Decorticate posturing and increased tone
Lower pontine to upper medullary ↓	Deep coma		Midposition and fixed	Absent	Flaccid: (1) retained bilateral extensor plantars, (2) occasional flexor responses in the lower limbs
Medullary (terminal)	Deep coma	Irregular breathing interrupted by deep sighs, gasps, and then terminal apnea	May be unequal	Absent	Flaccid

Modified from Plum F, Posner JB. Diagnosis of Stupor and Coma. Philadelphia: 1966; FA Davis.

TABLE 66.3

Brain Tissue Herniation Syndromes

Syndrome	Clinical Features
Foramen Magnum	
Herniating tissue: downward mesial displacement of cerebellar hemispheres *Compression:* unilateral or bilateral medulla by ventral parafollicular or tonsillae through foramen magnum	Episodic tonic extension with opisthotonic posturing, leading to quadriparesis Changes in ABP and heart rate Ataxic breathing Small pupils and disturbance of conjugate gaze
Central Tentorial	
Herniating tissue: downward displacement of one or both cerebral hemispheres *Compression:* diencephalon and midbrain through tentorial notch	ICP is raised Bilateral decorticate or decerebrate posturing Nerve palsy of cranial nerves III and VI Upward herniation occurs if supratentorial ventricles are decompressed in presence of cerebellar mass
Uncal (Lateral Transtentorial)	
Herniating tissue: medial temporal lobe (uncus and parahippocampal gyrus) forced into the incisura *Compression:* midbrain and posterior cerebral artery	ICP is raised Contralateral hemiparesis Ipsilateral pupillary dilatation and ptosis Unilateral or bilateral occipital lobe infarction Obstructive hydrocephalus from compression of aqueduct or perimesencephalic cistern Regions of necrosis and hemorrhage in tegmentum, subthalamus, midbrain, and upper pons
Cingulate	
Herniating tissue: cingulate gyrus herniates under the anterior falx *Compression:* anterior cerebral artery	Infarction of regional tissue Contralateral lower extremity paresis

ABP, arterial blood pressure; ICP, intracranial pressure.

Physiology of the Intracranial Vault

A physiologic process underlies the clinical picture of intracranial hypertension, and this section of the chapter will familiarize the pediatric intensivist with new approaches to understanding the hydrodynamic function of the intracranial vault. In other words, what happens before brain tissue shifts occur? Most of the developments in this field have occurred in the setting of adult neurosurgery and critical care. In common with any aspect of physiology, the tasks have been straightforward: Can it be measured? Can it be modeled? How do the models help in the understanding of the underlying homeostasis and the mechanism of derangement and perturbation? These topics are highlighted to demonstrate the obvious application to pediatric critical care—that is, use of this form of cerebral monitoring and potential approaches to ICP assessment. In many specific conditions, however, knowledge is still lacking with regard to which parts of the adult-generated theory may be fully applicable to children.

Cerebrospinal Fluid

Eighty percent of cerebrospinal fluid (CSF) is produced in the choroid plexus of the lateral and fourth (IV) ventricles. The remainder is produced in the interstitial space and ependymal lining. In the adult, the normal CSF volume is 150 mL (50% intracranial and the rest intraspinal). In the neonate, CSF volume is 50 mL. The rate of CSF production across all ages is 0.15 to 0.30 mL/min.

There are two pathways for CSF circulation: a major, “adult,” pathway, with CSF absorption through arachnoid villi (arachnoid granulation) into the venous sinuses, and a minor, “infantile,” pathway, with CSF drainage through the ventricular ependyma, the interstitial and perivascular space, and recently identified perivenous lymphatics. The need for CSF circulation begins early during intrauterine development because the choroid plexus is formed during the first trimester. Because arachnoid granulations do not appear until just before birth, it is unlikely that CSF reabsorption via the adult route of circulation is the major pathway during infancy. In fact, there is some evidence that arachnoid granulations continue to develop well into the second decade, so the infantile route of circulation may be significant in childhood.

Intracranial Pressure and Cerebrospinal Fluid Circulation

The brain is an expansile structure that expands and contracts with each beat of the heart. Because there are no valves within the venous drainage from the brain, any changes in intrathoracic pressure are transmitted to ICP. Such phenomena can be seen and palpated simply through the examination of a baby's fontanelle and quantified with CSF pressure recording. Once the cranial sutures have fused, any change in cerebral blood volume (CBV) on the arterial-to-arteriolar side of the

cerebral circulation must be compensated by either reduction in cerebral venous volume or phasic movement of CSF out of the intracranial vault through the foramen magnum. Such expansion of the cerebral mantle with compression of the lateral ventricles during systole and movement of CSF through the aqueduct of Sylvius and to-and-fro through the foramen magnum was first visualized with pneumoencephalography. These changes now can be seen more easily with dynamic magnetic resonance imaging (MRI). Inevitably a lag phase exists between the systolic increase in CBV and the effect of the compensatory mechanisms so that CSF pressure increases to reflect, in part, the systolic waveform. The CSF pressure waveform is not an exact replica of the arterial waveform because it has been "filtered" by the combined effects of arterial wall compliance of the cerebral arteries, cerebrovascular resistance, and intracranial compliance (Fig. 66.1).[1]

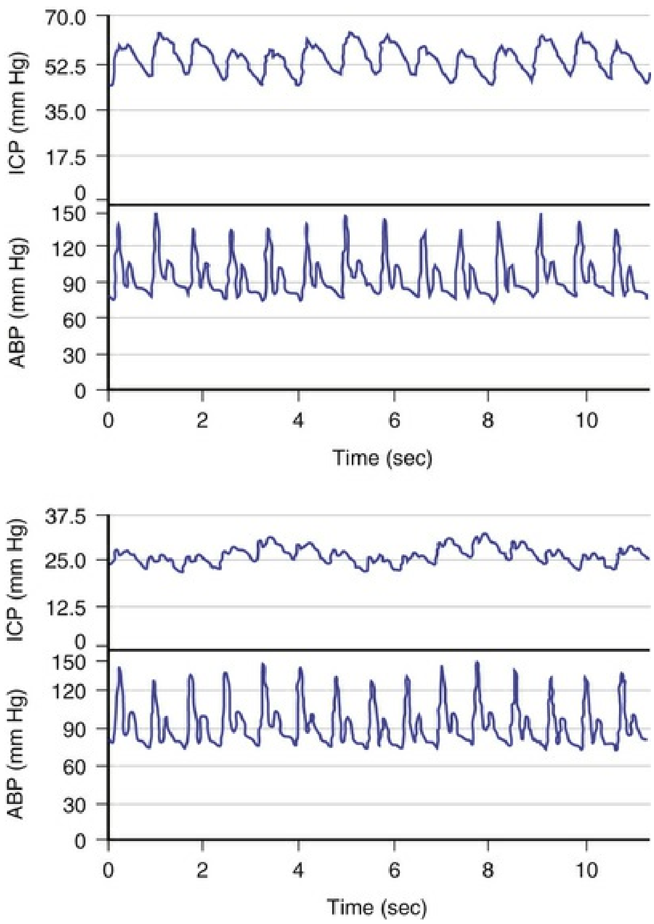

FIG. 66.1 Examples of waveforms of intracranial pressure (ICP) and arterial blood pressure (ABP) recorded at a high level of ICP *(upper plots)* and a lower level of ICP *(lower plots)*. Note that the pattern of ABP waveform is relatively invariant, but ICP changes its shape considerably. (From Pickard JD, Czosnyka M, Steiner LA. Raised intracranial pressure. In: Hughes RAC, ed. Neurological emergencies. London: BMJ Publishing Group; 2003:I.)

Hydrodynamic Model of Intracranial Pressure

ICP is a function of the circulation of CBF and CSF in which ICP is related to a

vascular component ($ICP_{vascular}$) and a CSF component (ICP_{CSF}). There is considerable interest in modeling these relationships as an aid to understanding some of the complex phenomena seen in critically ill patients. The vascular component is difficult to express quantitatively.[2] It is probably derived from the pulsation of CBV that is detected and averaged by nonlinear mechanisms of regulation of CBV. More generally, multiple variables such as the ABP, autoregulation, and cerebral venous outflow contribute to the vascular component and circulation of CSF and movement of interstitial fluid into the ventricles and subarachnoid space contributes the remainder. Drainage is largely passive via arachnoid villi and granulations into the superior sagittal sinus and spinal root sleeve venous drainage. Some drainage, which is currently unquantifiable, occurs through the olfactory bulb and mucosa into the deep cervical lymphatics.

The equation by Davson and colleagues[3] describes the immediate relationships controlling CSF pressure, in which ICP_{CSF} = (resistance to CSF outflow) × (CSF formation) + (pressure in sagittal sinus). Normal values for sagittal sinus pressure, CSF formation rate, and resistance to CSF outflow are 5 to 8 mm Hg, 0.3 to 0.4 mL/min, and 6 to 10 mm Hg/mL/min, respectively. In most clinical situations, sagittal sinus pressure stays constant or is coupled to central venous pressure. In practice, measured ICP is often greater than the value calculated using the equation. The difference is due to a vascular component, which is probably a result of pulsation in the arterial bed and is determined by the interaction between pulsatile arterial inflow and venous outflow curves, cardiac function, and cerebral vasomotor tone. With these two components—vascular and CSF—taken together, Fig. 66.2 shows the hydrodynamic model of CBF and CSF circulation and the equivalent electrical circuit analog.[4] Such models can be used to interrogate ICP and CSF dynamics clinically. For example, Kashif and associates described a model-based noninvasive estimation of ICP from middle cerebral artery (MCA) blood flow velocity using transcranial Doppler (TCD) and ABP waveforms.[5] Using 35 hours of data from 37 patients with severe TBI, the authors generated ICP estimates and achieved a mean error (bias) of 1.6 mm Hg.

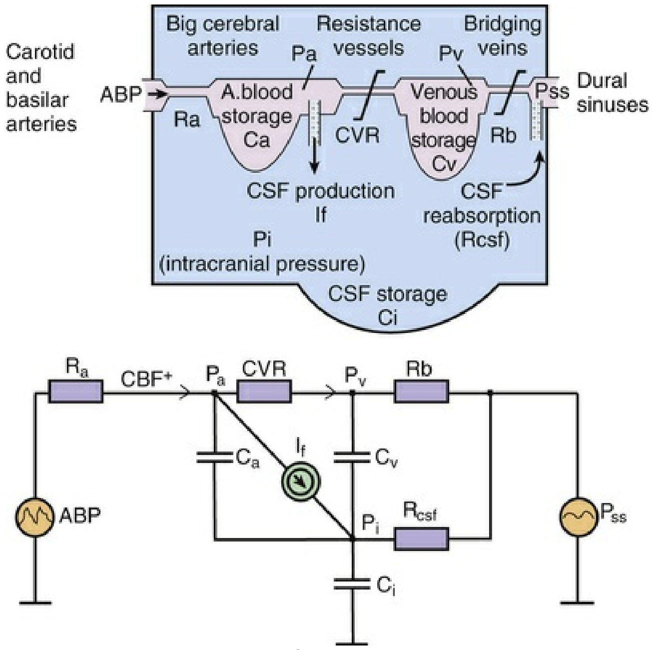

FIG. 66.2 Hydrodynamic model of cerebral blood and cerebrospinal fluid (CSF) circulation *(upper plot)* and its electrical equivalent *(lower plot)*. *ABP*, arterial blood pressure; *CBF*, cerebral blood flow. (From Czosnyka M, Piechnik S, Richards HK, et al. Contribution of mathematical modelling to the bedside tests of cerebrovascular autoregulation. J Neurol Neurosurg Psychiatry. 1997;63:721–731.)

Cerebral Vasodilation and Cerebrospinal Fluid Pressure

Three major factors regulate CBF: cerebral perfusion pressure (CPP), partial pressure of arterial carbon dioxide ($PaCO_2$), and partial pressure of arterial oxygen (PaO_2). Hypercapnia causes cerebral vasodilatation, increases CBF, and increases ICP. Hypoxia also causes cerebral vasodilatation and a rise in ICP. CPP is taken as the difference between mean ABP and ICP and represents the pressure gradient acting across the cerebrovascular bed; therefore it is an important factor in regulation of CBF.[6] Under normal circumstances, over a wide range of CPP, CBF is autoregulated (ie, it remains constant when CPP or ABP varies). Thus in regard to the effect of this phenomenon on ICP, active cerebral arteriolar constriction occurs and ICP consequently falls to maintain CBF when ABP is increased (ie, hypertension). At the other extreme, systemic hypotension (within the autoregulatory range) provokes cerebral vasodilatation and an increase in ICP. When autoregulation is defective, ICP increases and decreases with ABP (Figs. 66.3 and 66.4).[4,6]

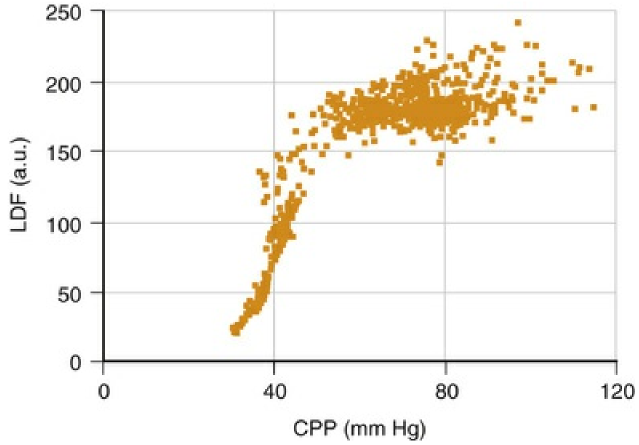

FIG. 66.3 Pressure autoregulation where cerebral blood flow (CBF) stays constant. CBF is measured with laser Doppler flowmetry (LDF) (*y*-axis). During changes in cerebral perfusion pressure (CPP) (*x*-axis), CBF remains constant until a critical threshold is reached, below which CBF falls passively with decreasing CPP.

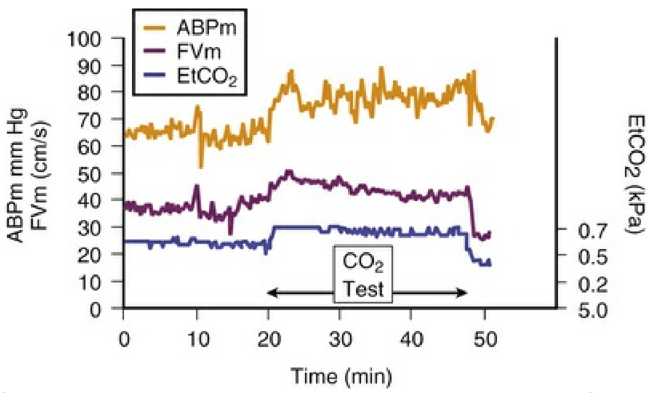

FIG. 66.4 Cerebral vessels dilate when arterial content of carbon dioxide (here measured with end-tidal carbon dioxide [E_tCO_2]) increases. A rise in cerebral blood flow (here assessed with transcranial Doppler velocity [FVm]) also increases.[6] *ABPm*, mean blood pressure.

In practice, measurement of ICP can be used to estimate the CPP when it is the most significant "downstream" pressure acting on vascular perfusion. However, in some instances, venous pressure may be of more significance, such as critical Fontan circulation.

Cerebral Perfusion Pressure and Autoregulation

In adults, the lower limit for CPP is taken as a threshold of 60 to 70 mm Hg. In children, however, it is evident from measurement of normal ABP that the lower limit for CPP must be lower than this adult level for much of childhood (Fig. 66.5).[7] A new concept that has arisen in the adult critical care literature is worth considering in this context. The idea is that an autoregulatory reserve exists that is considered to be the difference between current mean CPP and the lower limit of autoregulation.[8] This reserve may become exhausted. Alternatively, it may change over time, and it has been argued that the border between adequate and nonadequate CPP should be

assessed individually and frequently.

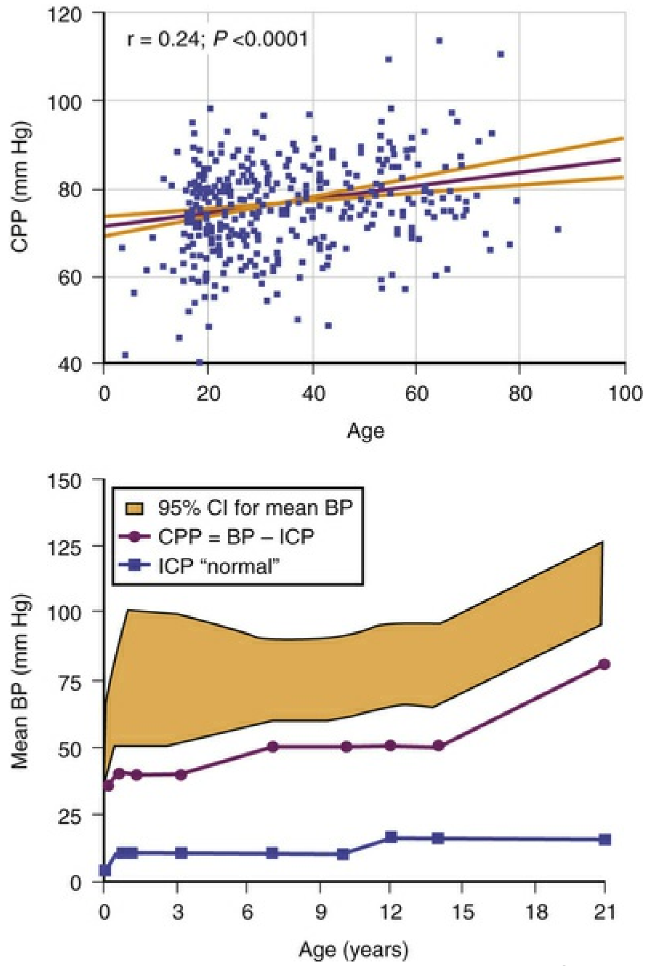

FIG. 66.5 The empiric relation between cerebral perfusion pressure (CPP) and age in nearly 400 adults after head injury *(top panel)*. Estimated lower limit of CPP by age in the pediatric range on the basis of normal blood pressure (BP) and intracranial pressure (ICP) data *(bottom panel)*.[7]

How is this assessment performed? Autoregulation of CBF may be assessed by artificial manipulation of ABP with medication, but only at infrequent intervals and with the risk that the drugs used may have a direct cerebrovascular effect. Alternatively, transient hyperemia after transient carotid compression has been used as an all-or-none index of whether autoregulation is intact. A more sophisticated approach is to examine the effect of natural variation in ABP; however, this technique requires precise signal processing. For example, to date, the most robust clinical method is to monitor the slow fluctuations in ABP that last from 30 seconds to a few minutes and are almost always present in patients who undergo ventilation[9,10]; the rate of change observed is usually sufficient to provoke a noticeable vasomotor response. Fig. 66.6 shows that continuous monitoring of cerebrovascular reactivity is possible with this method even during large spontaneous ICP waves (B and plateau waves, discussed later in this chapter).[10,11]

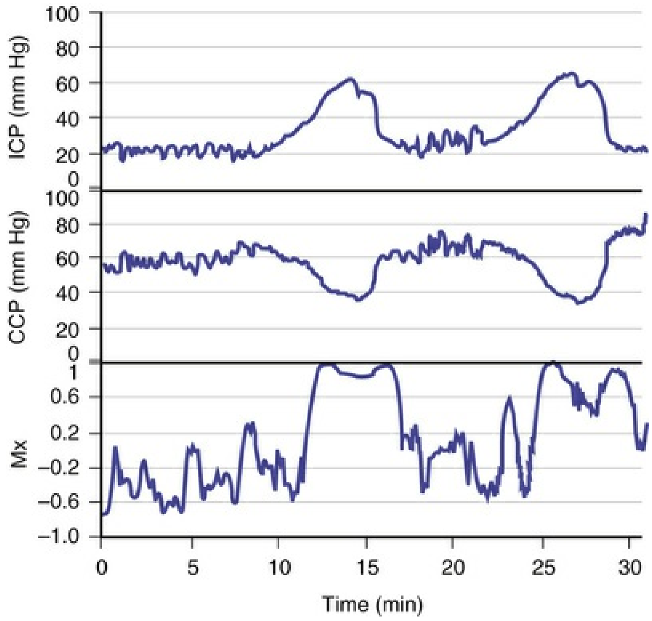

FIG. 66.6 Continuous monitoring of cerebral autoregulation during plateau waves of raised intracranial pressure (ICP). Positive values of the autoregulation index (Mx) indicate faulty autoregulation.[10] Autoregulation fails during the waves, when cerebral vasodilation occurs.[11] *CPP*, cerebral perfusion pressure.

Measurement of Intracranial Pressure

Monitoring Devices

ICP monitoring devices can be categorized according to the anatomic site of placement and the manner in which the pressure record is transduced. For example, in babies, surface tonometry, applied to the anterior fontanelle, was an early method used for noninvasive transduction of the ICP waveform. This method, however, is limited because the force of applanation influences the pressure record. More standard approaches for the measurement of ICP rely on manometry of catheters placed in the ventricular system or in other CSF space. Alternatively, pressure sensors may be placed within the brain.

The complications of ICP monitoring include infection, hemorrhage, CSF over drainage, and monitor malfunction. The overall incidence of infection for the various forms of ICP monitors is not significantly different regardless of their location, but the severity of infection may differ slightly depending on the anatomic site of the device. Hemorrhage is a rare complication of ICP monitoring and is a direct result of surgical placement of the device. Over drainage of ventricular catheters can result in rapid emptying of the ventricular system and accumulation of subdural hematomas. Close attention must be made to prevent drainage systems from being placed too low or falling to the floor. This complication is most serious when intraventricular pressure is monitored in children with hydrocephalus. Over drainage also may result in pneumocephalus.

Overall, an intraventricular drain connected to an external pressure transducer is still considered the gold standard for measuring ICP.[12,13] ICP can be controlled by

CSF drainage, and the transducer can be adjusted to zero externally. After 5 days of monitoring, however, the risk of infection starts to increase, with an overall risk estimated to be about 5%.[14] Insertion of the ventricular catheter may be difficult or impossible in cases of advanced brain swelling. As an alternative, modern catheter-tipped ventricular, subdural, or intraparenchymal microtransducers have been used (the most popular types are the Camino ICP Bolt, Camino Laboratories, San Diego, California, and Codman MicroSensor, Johnson and Johnson Professional Inc, Raynham, Massachusetts). These microtransducers are said to reduce the infection rate and risk of hemorrhage and have excellent metrologic properties.[15] One disadvantage of microtransducer systems is that they cannot, in general, be readjusted to zero after insertion, and considerable zero drift sometimes can occur in long-term monitoring.[16]

Regarding other forms of monitoring, contemporary epidural sensors are much more reliable now than they were 10 years ago. Nevertheless, the question as to whether epidural pressure can express ICP with confidence and under all circumstances is still unanswered. Lumbar CSF pressure is seldom measured in patients receiving neurointensive care. This form of assessment of craniospinal dynamics is more often used in the assessment of hydrocephalus and benign intracranial hypertension. It is unreliable if the instantaneous value of the fluid column pressure is recorded; at least 30 minutes averaging in resting conditions (with a period of overnight monitoring as the gold standard) is the desired requirement. Finally, attempts to monitor ICP noninvasively are still in a phase of technical evaluation, with the most promising methods based on TCD of the MCA,[5] ultrasound of the optic nerve sheath,[17,18] and measurement of intraaural pressure waves.[19,20]

Noninvasive Inference of Intracranial Pressure

It would be helpful to measure ICP or CPP without invasive transducers. To this end, TCD examination[5] and tympanic membrane pressure waves[19-21] have been suggested as front-runners in the field. The description of TCD sonography by Aaslid and colleagues[22] permitted bedside monitoring of one index of CBF noninvasively, repeatedly, and even continuously. The problem has been that it is a “big tube technique” that measures flow velocity in branches of the circle of Willis, most commonly the MCA. Compliant branches of the MCA can be compared with two physiologic pressure transducers. The pattern of blood flow within these vessels is certainly modulated by transmural pressure—that is, CPP and the distal vascular resistance (also modulated by CPP). The calibration factors and compensation for unknown nonlinear distortion are unknown.

The measurements that are made with TCD include Vmean, mean velocity (cm/sec); peak systolic velocity (PSV; cm/sec); and end-diastolic velocity (EDV; cm/sec). The *resistive index* (RI) is equals [PSV-EDV] ÷ PSV. The *pulsatility index* (PI) can also be calculated with these values, where PI equals [PSV-EDV] ÷ Vmean. As can be seen, the PI and RI are mathematically coupled (PI = [RI × PSV] ÷ Vmean). Reasonable correlation exists between the PI and CPP after severe TBI, but absolute measurements of CPP cannot be extrapolated.[23] Other investigators have suggested that “critical closing pressure” derived from MCA flow velocity and the ABP waveform approximated the value of ICP.[24] The accuracy of this method, however, is

far from satisfactory.[25] Aaslid and colleagues[26] suggested that an index of CPP could be derived from the ratio of the amplitudes of the first harmonics of the ABP and the MCA velocity (detected with TCD sonography) multiplied by mean flow velocity. Another method for the noninvasive assessment of CPP is derived from mean ABP multiplied by the ratio of diastolic to mean flow velocity.[27] This estimator can predict real CPP—in the adult range (60 to 100 mm Hg)—with an error of less than 10 mm Hg for more than 80% of measurements. The method is of potential benefit for continuous monitoring of changes in real CPP over time in situations where direct measurement of CPP is not readily available. A more complex method aimed at the noninvasive assessment of ICP has been introduced and tested by Schmidt and coworkers.[28] This method is based on the presumed linear transformation between ABP and ICP waveforms. However, all of these techniques still require validation in pediatric series.

Last, there is one other potential method for predicting increased ICP that has emerged from the adult literature and is now being tested in children. Optic nerve sonography can be used to assess enlargement of the optic nerve sheath, and it is sheath diameter that appears to be directly related to the level of ICP.[29] Le and colleagues[30] studied 64 children, 24 (37%) of whom had a confirmed diagnosis of increased ICP. An optic nerve sheath diameter greater than 4 mm in subjects younger than 1 year and greater than 4.5 mm in older children was considered abnormal. The sensitivity of optic nerve sheath diameter as a screening test for increased ICP was 83% (95% confidence interval [CI], 0.60 to 0.94), specificity was 38% (95% CI, 0.23 to 0.54), positive likelihood ratio was 1.32 (95% CI, 0.97 to 1.79), and negative likelihood ratio was 0.46 (95% confidence interval, 0.18 to 1.23). Taken together, it is clear that this technique may be useful, but currently it is inadequate as an aid to decision making about whether raised ICP is present in a particular child.

Pressure Compartments

In a fluid-filled container, pressure is the same wherever one chooses to measure it within that space. Generally, uniformly distributed ICP can be seen only when CSF is circulating freely among all of its natural pools, equilibrating pressure everywhere. When little or no CSF volume is left (because of brain swelling), the assumption of one uniform value of ICP is questionable. (It is for this reason that brain tissue shift and herniation occur: Tissue shifts in the direction of the pressure gradient.) It is worth remembering that with the commonly used catheter-tipped, intraparenchymal probes, the measurement of pressure is at a particular point in space, an area of cortex within a hemisphere, and the ICP may merely reflect pressure in that compartment rather than be representative of pressure within the ventricular system (ie, real CSF pressure).[31]

Analysis of Intracranial Pressure

Normal Values in Intracranial Pressure Monitoring

Establishing a universal "normal value" for ICP is difficult because it depends on age, body posture, and clinical condition. In the horizontal position, a normal ICP value in healthy adults was reported to be within the range of 7 to 15 mm Hg.[32] In

the upright position, ICP is a negative value, with a mean of around ~10 mm Hg but not exceeding ~15 mm Hg.[33] In infants and children, normal values for ICP, usually taken at the time of a "negative" diagnostic lumbar puncture, are lower than the adult values and are probably between 5 and 10 mm Hg.

The definition of a raised ICP value depends on the specific disease. In hydrocephalus, a pressure above 15 mm Hg can be regarded as elevated. After head injury, any pressure above 20 mm Hg is considered abnormal, and aggressive treatment is usually started with values above 25 mm Hg.[34] Also, in most cases, ICP varies with time. Decent averaging for at least 30 minutes is needed to calculate "mean ICP." The patient should be in a horizontal position during the measurement, and movement should be avoided.

Normal Trends in Intracranial Pressure and Waveform Analysis

Overnight monitoring, during natural sleep, provides a "grand average" with a good description of the dynamics of ICP. When monitored continuously in acute states (eg, in the presence of head injury, poor-grade subarachnoid hemorrhage, and intracerebral hematoma), changes in the time-averaged mean ICP may be classified into relatively few patterns (Fig. 66.7).[35] The first pattern, low and stable ICP (below 20 mm Hg), is seen after uncomplicated head injury (Fig. 66.7A). Such a pattern also is seen commonly in the initial period after brain trauma before brain swelling evolves. The second pattern, high and stable ICP (above 20 mm Hg), is the most common pattern to follow head injury (Fig. 66.7B). The third pattern is vasogenic waves—that is, B waves (Fig. 66.7C) and plateau waves (Fig. 66.7D). The fourth pattern is ICP waves related to changes in ABP and hyperemic events (Fig. 66.7E to G). The final pattern, refractory intracranial hypertension (Fig. 66.7H), usually leads to death unless surgical decompression is undertaken.

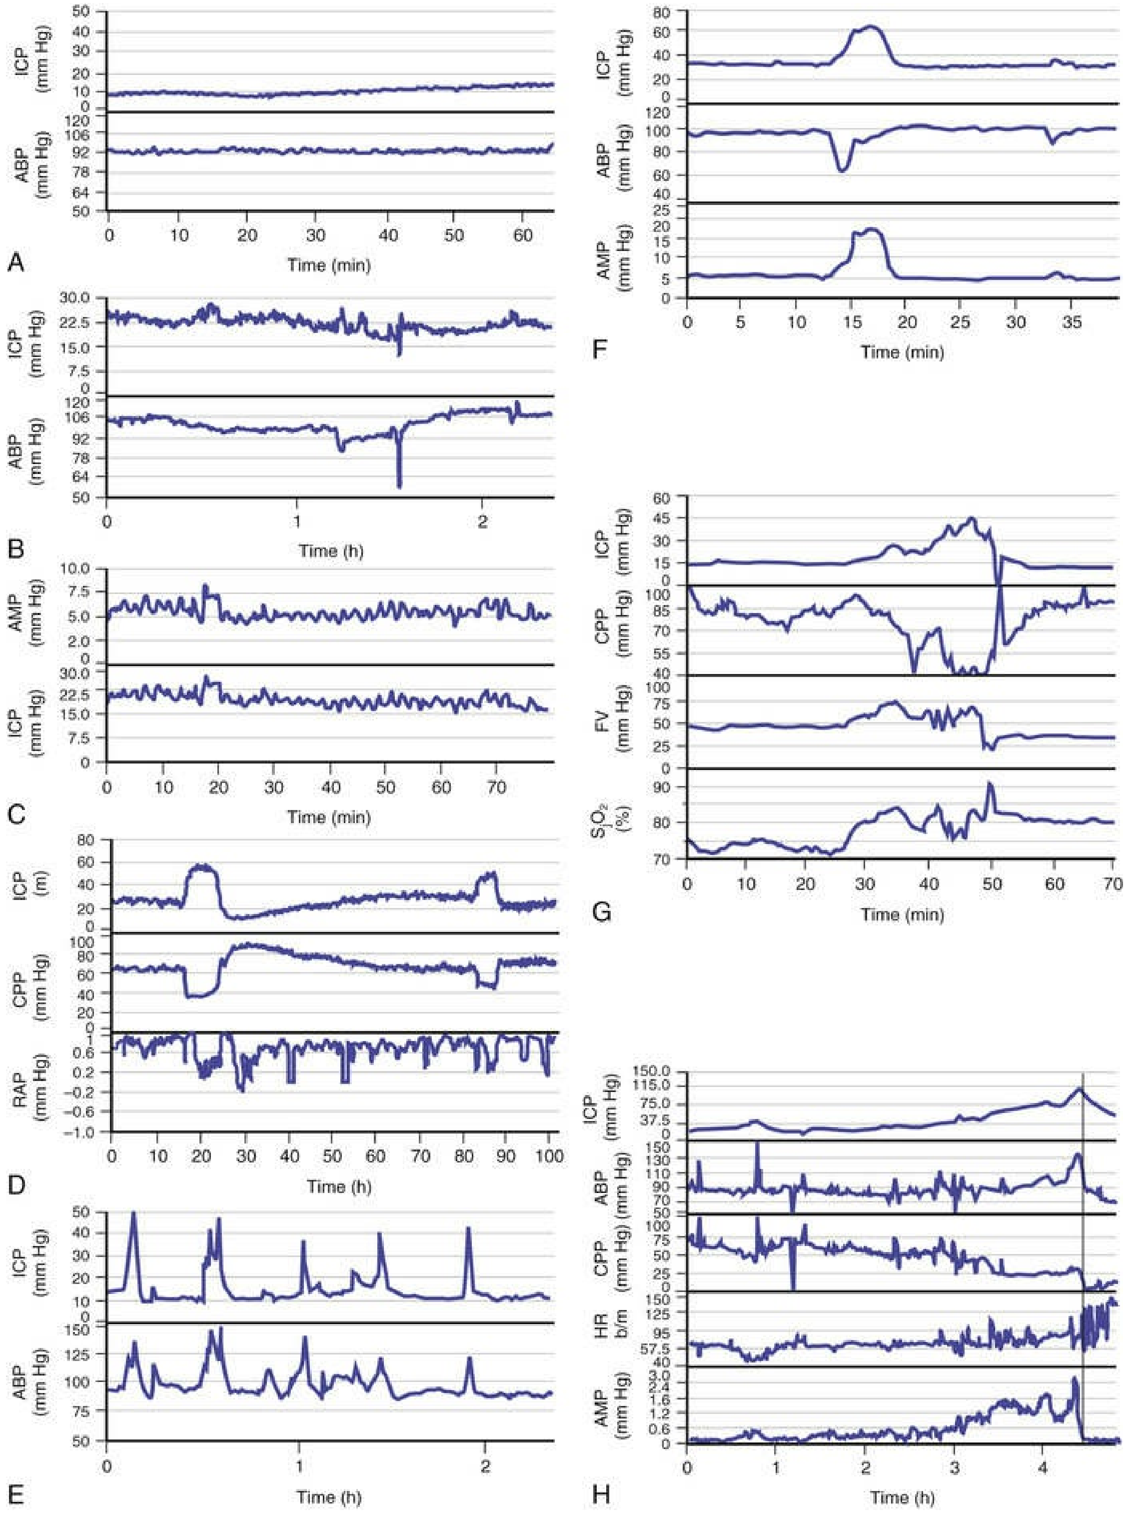

FIG. 66.7 Examples of intracranial pressure (ICP) recording in various clinical scenarios after head trauma[35]; note the different scales. (A) Low and stable ICP: mean arterial blood pressure (ABP) is plotted in the *bottom panel.* (B) Stable and elevated ICP: such a picture can be seen most of the time in patients with head injuries. (C) B waves of ICP: these are seen both in mean ICP and spectrally resolved pulse amplitude of ICP (AMP). They also are usually seen in a plot of time-averaged ABP, but not always. (D) Plateau waves of ICP: cerebrospinal compensatory reserve is usually low when waves are recorded (the correlation coefficient between AMP and mean ABP, RAP, is close to +1). At the top of the waves, during

maximal vasodilatation, integration between pulse amplitude and mean ICP fails, as indicated by a fall in RAP. After the plateau wave, ICP usually falls below the baseline level and cerebrospinal compensatory reserve becomes better. *CPP,* cerebral perfusion pressure. (E) High, spiky waves of ICP caused by sudden increases in ABP. (F) Increase in ICP caused by temporary decrease in ABP. (G) Increase in ICP of hyperemic nature: both blood flow velocity (FV) and jugular bulb oxygen saturation (SjO_2) increase in parallel with ICP. (H) Refractory intracranial hypertension: ICP increases within a few hours to 100 mm Hg. The *vertical line* denotes the likely moment when the vasomotor centers in the brain stem became ischemic. At this point the heart rate (HR) increased and CPP decreased abruptly. Note that pulse amplitude of ICP (AMP) disappeared around 10 minutes before this terminal event.

In addition to these patterns, more information can be gained from analyzing the ICP waveform. The ICP waveform consists of three components, which overlap in the time domain but can be separated in the frequency domain (Fig. 66.8).[35,36] The pulse waveform has several harmonic components; of these, the fundamental component has a frequency equal to the heart rate. The amplitude of this component (AMP) is useful for the evaluation of various indices. The respiratory waveform is related to the frequency of the respiratory cycle (8 to 20 cycles/min). “Slow waves” are usually not as precisely defined as in Lundberg's original work[37]—that is, all components that have a spectral representation within the frequency limits of 0.05 to 0.0055 Hz (20-second to 3-minute period) are considered slow waves. The magnitude of these waves can be calculated as the square root of the power of the signal, of the passband, or of the equivalent frequency range at the output of the digital filter.

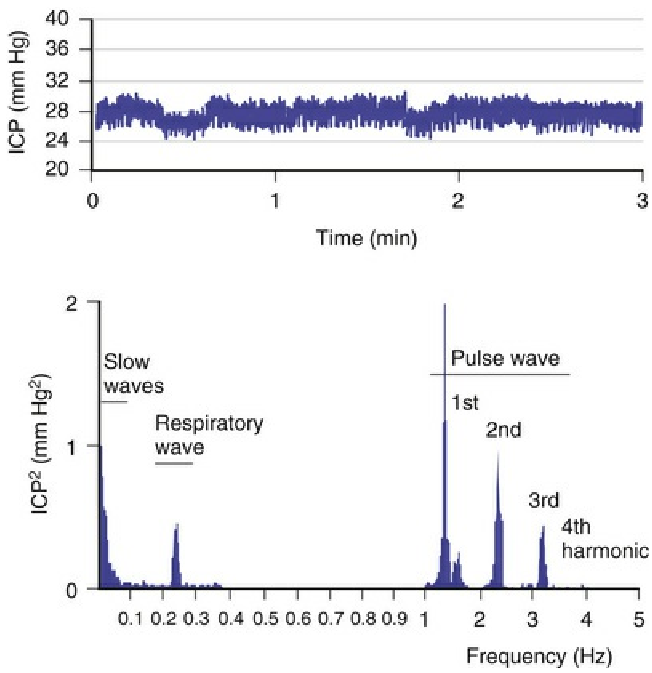

FIG. 66.8 Example of intracranial pressure (cICP) recording showing pulse, respiratory waves, and “slow waves” overlapped in the time domain *(top panel)* and separated in the frequency domain *(bottom panel)*.[36]

Assessment of Pressure-Volume Compensatory Reserve and Cerebrovascular Pressure Reactivity

Theoretically, the compensatory reserve in intracranial hydrodynamics can be studied through the relation between ICP and changes in volume of the intracerebral space, known as the pressure-volume curve.[38,39] For example, the RAP index, an index of reserve based on the correlation coefficient (R) between AMP amplitude (A) and mean pressure (P), can be derived. This calculation can be done in real time with bedside computing to calculate the linear correlation between consecutive, time-averaged data points of AMP and ICP (usually 40 such samples) acquired over a reasonably long period to average over respiratory and pulse waves (usually 6- to 10-second epochs). The RAP index indicates the degree of correlation between AMP and mean ICP over short periods (~4 minutes). A RAP index close to zero indicates a lack of synchronization between changes in AMP and mean ICP. This index denotes good pressure-volume compensatory reserve at low ICP (ie, a change in volume produces little or no change in pressure) (Fig. 66.9).[40] When the RAP index rises to +1, AMP varies directly with ICP and indicates that the "working point" of the intracranial space shifts to the right toward the steep part of the pressure-volume curve. Here compensatory reserve is low; therefore any further rise in volume may produce a rapid increase in ICP. After head injury and subsequent brain swelling, the RAP index is usually close to +1. With any further increase in ICP, AMP decreases and RAP values fall below zero. This phenomenon occurs when cerebral autoregulatory capacity is exhausted; the pressure-volume curve bends to the right, the capacity of cerebral arterioles to dilate in response to a fall in CPP is exhausted, and the arterioles tend to collapse passively. This phenomenon indicates terminal cerebrovascular derangement with a decrease in pulse pressure transmission from the arterial bed to the intracranial compartment.

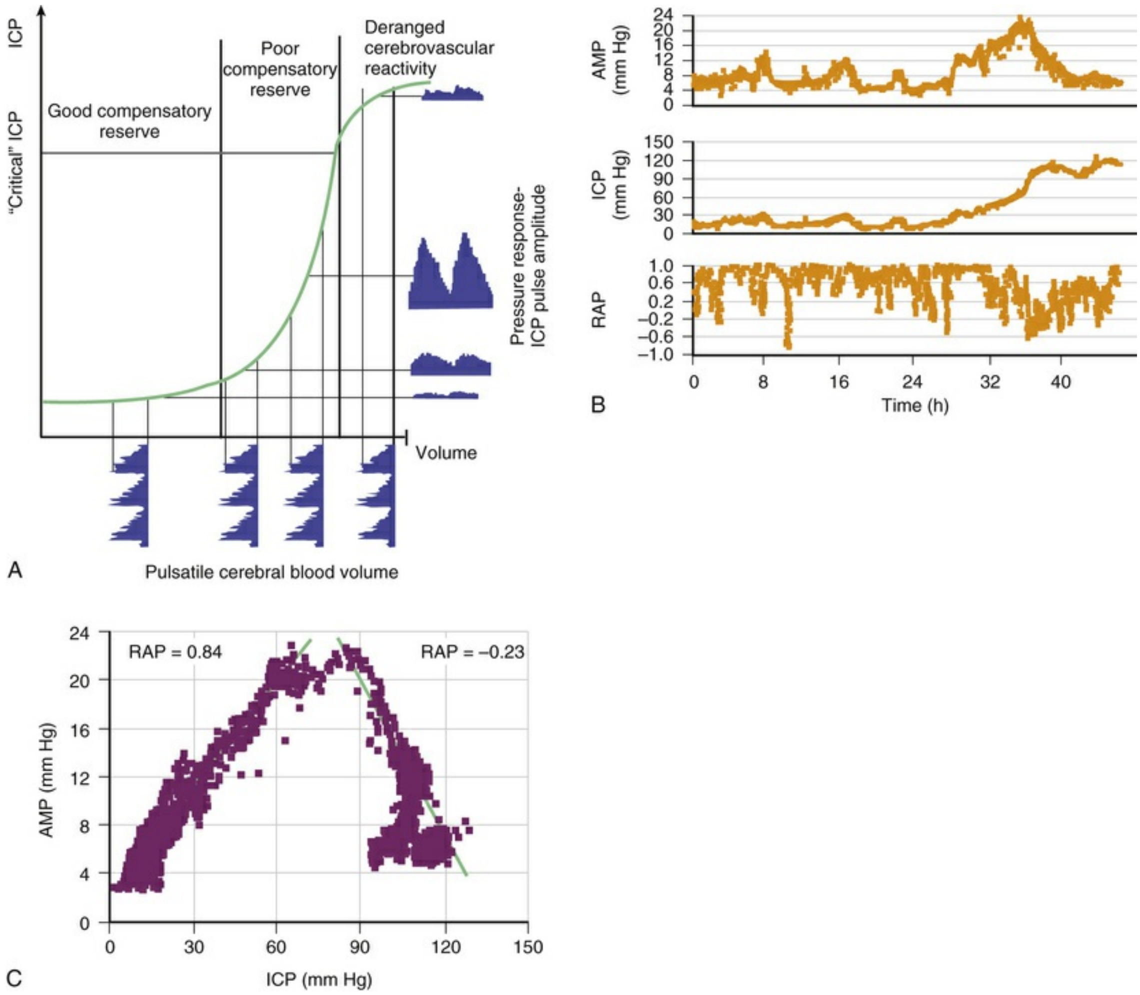

FIG. 66.9 (A) In a simple model, pulse amplitude of intracranial pressure (ICP) (AMP, expressed along the *y*-axis on the right side of the panel) results from pulsatile changes in cerebral blood volume (expressed along the *x*-axis) transformed by the pressure-volume curve. This curve has three zones: a flat zone, expressing good compensatory reserve; an exponential zone, depicting poor compensatory reserve; and a flat zone again, seen at very high ICP (above the "critical" ICP), depicting derangement of normal cerebrovascular responses. The pulse amplitude of ICP is low and does not depend on mean ICP in the first zone. The pulse amplitude increases linearly with mean ICP in the zone of poor compensatory reserve. In the third zone, the pulse amplitude starts to decrease with rising ICP. (B) Example of the relation between AMP and mean ICP recorded during a 46-hour period, during which terminal intracranial hypertension developed. Pulse amplitude increased first proportionally to the change in ICP but started to decrease when ICP increased above 80 mm Hg. (C) The regression plot between AMP and ICP indicates a biphasic relation of positive and negative slopes. The correlation coefficient between AMP and ICP (RAP) was positive before 32 hours but negative after that; this indicated terminal cerebrovascular deterioration.[40]

Another ICP-derived index is the pressure-reactivity index (PRx), which incorporates the idea of assessing cerebrovascular reaction by observing the response of ICP to slow spontaneous changes in ABP (discussed previously). For example, when the cerebrovascular bed is normally reactive, any change in ABP

produces an inverse change in CBV and thus ICP. When cerebrovascular reactivity is disturbed, changes in ABP are transmitted passively to ICP. Again, with the use of computational methods similar to those used for the calculation of the RAP index, PRx is determined with the calculation of the correlation coefficient between 40 consecutive, time-averaged data points of ICP and ABP. A positive PRx signifies a positive gradient of the regression line between the slow components of ABP and ICP, which is suggested as being associated with passive behavior of a nonreactive vascular bed (Fig. 66.10A).[9] A negative value of PRx reflects a normally reactive vascular bed, because ABP waves provoke inversely correlated waves in ICP (Fig. 66.10B). In practice, this index correlates well with TCD ultrasonography indices of autoregulation.[9] Also, abnormal values of both PRx and RAP, which are indicative, respectively, of poor autoregulation or deranged cerebrospinal compensatory reserve, have been shown to be predictive of a poor outcome in adults after head injury.[8]

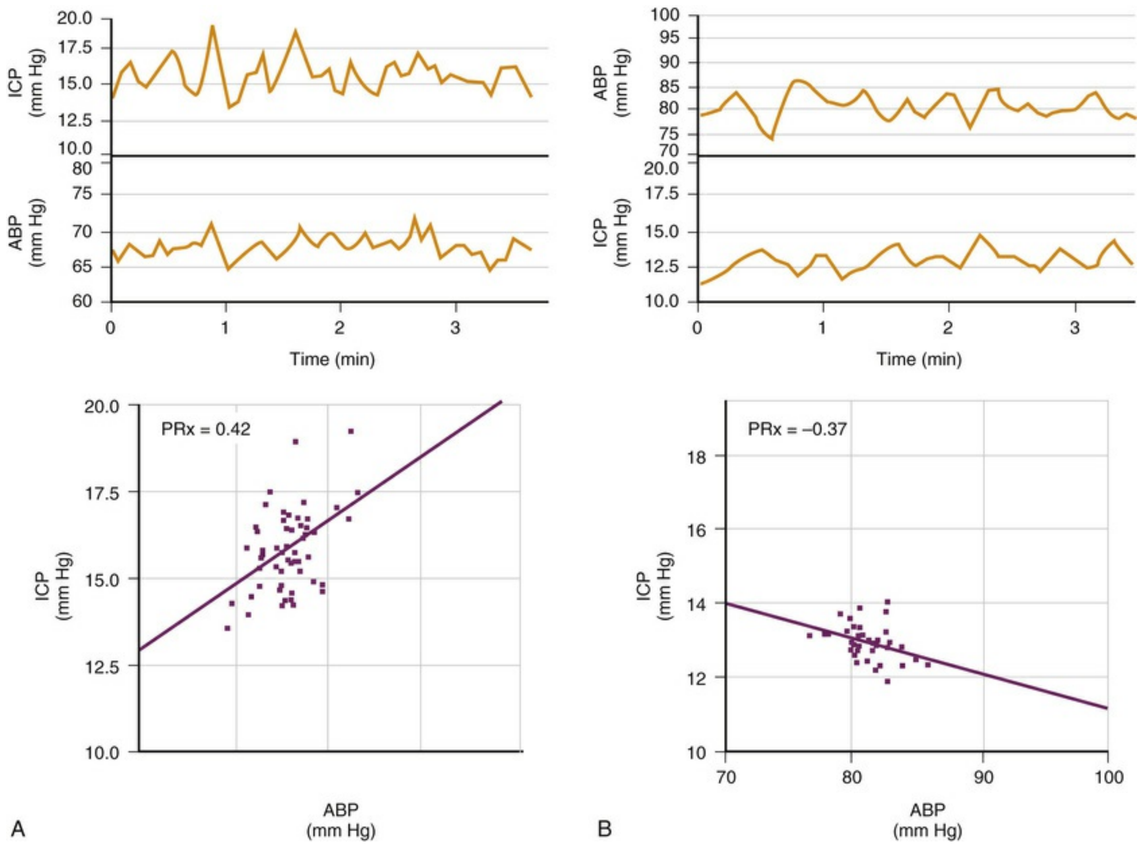

FIG. 66.10 Relation between slow waves of arterial pressure (ABP) and intracranial pressure (ICP). (A) Slow waves in ICP and ABP produce a positive correlation *(lower left panel)*, giving a positive value of the pressure-reactivity index (PRx), which indicates loss of cerebrovascular reserve. (B) Coherent waves both in ABP and ICP produced a negative correlation coefficient when plotted on the regression graph *(lower right)*, giving values of PRx that were clearly negative.

To date, there are few data on the use of these hydrodynamic indices in children. One report in 32 hydrocephalic children, however, examined maximum ICP, RAP index, magnitude of slow waves, and AMP in individuals presenting with possible

ventriculoperitoneal shunt dysfunction.[41] The authors concluded that, because of the association between abnormalities in the parameters studied and improvement in symptoms in patients undergoing shunt revision, such computerized ICP assessments are beneficial. In another study of 21 children with head injuries, Brady and colleagues[42] used continuous monitoring of the PRx and found this parameter to be associated with outcome. In addition, they found that impaired cerebrovascular pressure reactivity was evident at low levels of CPP. The implication is that PRx may be useful for defining age-specific and possibly patient-specific optimal targets for CPP (see the following section).

Monitoring Optimal Cerebral Perfusion Pressure Derived From Intracranial Pressure Parameters

Both the PRx and the RAP index can be used to evaluate secondary variables that combine the value of absolute ICP and CPP with information about the state of autoregulatory and compensatory reserves. In adults with head trauma, PRx plotted against CPP gives a U-shape curve that indicates, for most patients, a value of CPP for which pressure-reactivity is optimal.[8] This optimal pressure can be estimated with the plotting and analyzing of the PRx-CPP curve in sequential 6-hour periods; the greater the distance between the current and the "optimal" CPP, the more likely outcome will be poor. This potentially useful method attempts to refine the current approach to CPP-oriented therapy: Levels of CPP that are either too low (ischemia) or too high (hyperemia and a resulting increase in ICP) are detrimental. It has been suggested that CPP in adults should be optimized to maintain CPP in the most favorable global state.[8]

Quantifying the Cumulative Intracranial Pressure/Cerebral Perfusion Pressure Insult to the Brain

In adults with severe head injury, the cumulative insult to the brain can be quantified in a number of ways. For example, an average ICP above 25 mm Hg during the entire period of monitoring doubles the risk of death.[8] Averaged values of the RAP index and the PRx also are strong predictors of fatal outcome. Both these indices suggest that good vascular reactivity is an important element of brain homeostasis, which enables the brain to protect itself against an uncontrollable rise in intracerebral volume. Also, a low value of slow waves of ICP also is indicative of a fatal outcome after head injury. Because each of these parameters—ICP, PRx, and the power of ICP slow waves—is an independent predictor of outcome, these three variables, although mutually correlated, should be considered jointly in any analysis. With regard to mean CPP, it is now one of the variables that is actively targeted with treatment; therefore, it may have lost its predictive power for outcome. This fact does not mean that short-term decreases in CPP ("CPP insults") have become any more benign. Reductions in CPP below specific threshold values are associated with poor outcome. In cases of severe pediatric head injury, studies have defined the CPP associated with poor outcome as between 40 and 65 mm Hg. For example, Downard and coworkers[43] studied 118 children (mean age, 7 years) with an overall mortality rate of 28% and found that the CPP associated with survival was greater than 40 mm Hg. No further improvement in outcome was seen with mean CPP in deciles from 40

to 70 mm Hg.

Invasive Intracranial Pressure Monitoring in Clinical Care

Traditionally, ICP monitoring is performed via a ventriculostomy. Newer technologies rely on fiberoptic monitoring, with the catheter sensor-tip placed in the brain parenchyma. On reviewing the literature about ICP monitoring in severe TBI, three key observations emerge.

First, the use of invasive ICP monitoring in management of pediatric severe TBI is by no means universal around the world. In the United States there is variation in practice. For example in a large multicenter database (2001 to 2011) of 4667 children with TBI, there was significant between-hospital variation in ICP monitoring.[44] Overall, 55% of patients ($n = 2586$) received ICP monitoring. Observed hospital ICP monitoring rates were 14% to 83%. After adjustment for patient factors, 13% of the ICP monitoring variation was attributable to between-hospital variation. Hospitals with more observed ICP monitoring, relative-to-expected, and hospitals with higher patient volumes had lower rates of mortality or severe disability. After adjustment for between-hospital variation and patient severity of injury, ICP monitoring was independently associated with age 1 year and older (odds ratio, 3.1; 95% CI, 2.5–3.8) versus age younger than 1 year. Another study, this time using the US National Trauma Data Bank of pediatric TBI cases managed in levels I and II centers (2001 to 2006), found that ICP monitoring was undertaken in few pediatric patients with severe TBI.[45] Usage of ICP monitoring was associated with decreased mortality rate in only a small subset of the targeted population. In addition, children who received a monitoring device had longer hospital stay, longer PICU stay, and more ventilator days. These findings suggest that current use of ICP monitoring does not necessarily identify patients who are most likely to benefit from it.

Second, not all patients undergoing invasive ICP monitoring for severe TBI exhibit raised ICP. In a national study in the UK of all pediatric cases of severe TBI managed in the PICU (2001 to 2003), raised ICP was documented in only 49% (98 of 199 cases) of cases undergoing monitoring.[46] The authors found that of the variables significantly associated with raised ICP in univariate analyses (emergency department Glasgow Coma Scale [GCS] score, pupil reactivity, age, and the findings on admission computed tomography scans in relation to presence of subarachnoid hemorrhage, intracerebral hemorrhage, or traumatic axonal injury (TAI), and lateral ventricle appearance), only the presence of TAI retained an independent association with development of raised ICP in multivariate logistic regression. GCS ≤8 predicted raised ICP with sensitivity 80% and specificity 55% (positive predictive value 59%, negative predictive value 77%). "Any abnormality on CT" predicted raised ICP with sensitivity 91% and specificity 38% (positive predictive value 58%, negative predictive value 82%). And, as also reported by others,[47] the presence of raised ICP despite normal radiology and pupil responses likely reflect the known low sensitivity of CT for clinically significant TAI.

Third, it is now known that aggressive medical treatment of intracranial hypertension complicating severe TBI can be guided by one of two strategies, with no difference in outcome: use of ICP monitoring as a guide to therapy or use of

intensive clinical examination and serial CT scans to guide therapy.[48,49] In this 2012 study, in South America, 324 patients (13 years or older, 25% under 22 years of age) were randomly assigned to one of two specific protocols: guidelines-based management in which a protocol for monitoring intraparenchymal ICP was used or a protocol in which treatment was based on CT scans and clinical examination. The primary outcome was a composite of survival time, impaired consciousness, and functional status at 3 months and 6 months and neuropsychologic status at 6 months. There was no significant between-group difference in the primary outcome. Six-month mortality was no different between the groups (39% in the pressure-monitoring group and 41% in the imaging-clinical examination group). The median length of stay was similar in the two groups (12 days in the pressure-monitoring group and 9 days in the imaging-clinical examination group), although the number of days of brain-specific treatments (eg, administration of hyperosmolar fluids and the use of hyperventilation) was higher in the imaging-clinical examination group than in the pressure-monitoring group.

Taking everything together, it is clear that there is still much to learn in how we select patients for invasive monitoring and how we use the information from monitoring to guide our therapies. Even so, the authors' practice is to use invasive monitoring to guide treatment, rather than to rely solely on serial clinical examinations and CT imaging.

Intracranial Pressure and Cerebral Perfusion Pressure Target Levels

In adults, the threshold for initiating treatment of intracranial hypertension is taken as 20 to 25 mm Hg. It is likely that the ICP threshold for poorer outcome is similar across all ages and the second edition of the Brain Trauma Foundation's *Guidelines for the Acute Medical Management of Severe TBI in Infants, Children, and Adolescents*[34] concludes that treatment of raised ICP at a threshold of 20 mm Hg may be considered (level III evidence). In this regard, brief increases in ICP that return to normal in <5 min may be insignificant, but sustained increases of ≥20 mm Hg for ≥5 min likely warrant treatment. Despite this practice, it should be noted that the optimal ICP target or targets for pediatric TBI remain to be defined.

Normal values for mean arterial blood pressure and hence CPP are lower in children, particularly in infants and young children. Two assumptions are made when using calculated CPP to guide treatment. The first assumption is that the mean systemic arterial pressure is a good reflection of brain surface arteriolar pressure, and this may not be the case. The second assumption is that both pressures contributing to the calculation are calibrated to the same level. In the case of ICP monitoring via ventriculostomy, the point for zero calibration can be adjusted, although few reports discuss the exact details of calibration and zeroing. This adjustment is not possible with the fiber-tip intraparenchymal devices, for which the pressure is recorded at the tip of the sensor. If, in the case of ventricular monitoring, the zero point for ICP is taken as the level of the external auditory meatus and the zero point for blood pressure is taken as the level of the right atrium, then the actual CPP driving CBF would be lower than the simply calculated difference between the mean arterial blood pressure and the mean ICP. The magnitude of this difference is related to the product of the sine of the angle of elevation of the bed and the distance

between the two calibration points. In children, this difference is of the order of 5 mm Hg. However, if an intraparenchymal fiber-tip device is used and the bed is elevated beyond 30 degrees, the error could be doubled. Clinicians should therefore be cautious about how the data reporting exact critical CPP values are interpreted, particularly as few reports describe the methods of calibration in their practice. The 2012 Brain Trauma Foundation guidelines[34] conclude the following level III recommendation: A minimum CPP of 40 mm Hg may be considered in children with TBI, and a CPP threshold 40 to 50 mm Hg may be considered—there may be age-specific thresholds with infants at the lower end and adolescents at the upper end of this range. In adult patients, with respect to CPP, it appears that the critical threshold for cerebral ischemia generally lies in the region of 50 to 60 mm Hg,[50] and the Brain Trauma Foundation adult CPP guidelines therefore suggest "a general threshold in the realm of 60 mm Hg, with further fine-tuning in individual patients based on monitoring of cerebral oxygenation and metabolism and assessment of the status of pressure autoregulation."[51]

In 2014 a report from the Brain Trauma Foundation trac database of 317 pediatric severe TBI cases provided further insight in to age-related CPP thresholds and survival in children and adolescents.[52] The evidence suggests that CPP targets should be age specific: above 50 or 60 mm Hg in adults, above 50 mm Hg in 6- to 17-year-olds, and above 40 mm Hg in 0- to 5-year-olds. Furthermore, because systemic hypotension had an inconsistent relationship with events of low CPP, but elevated ICP did, the authors recommended that ICP should be controlled at all times, while also targeting systolic blood pressure in specific instances. ICP-directed therapies are discussed in the next section.

Clinical Utility of Intracranial Pressure Monitoring With Other Monitoring Modalities

The continuous measurement of ICP is an essential modality in most brain monitoring systems. After enthusiastic attempts to introduce newer modalities for brain monitoring (eg, tissue oxygenation, microdialysis, cortical blood flow, TCD ultrasonography, jugular bulb oxygen saturation, and near infrared spectroscopy), it is becoming increasingly obvious that ICP is robust, only moderately invasive, and can be realistically conducted in most critical care units. As noted earlier, ICP measurement is a complex modality that contains information about compensatory mechanisms intrinsic to the brain and regulation of CBF. Thus continuous monitoring is required to control raised ICP. For example, most authors agree that ICP should be measured in patients with acute states such as severe TBI, poor-grade subarachnoid hemorrhage, and intracerebral hematoma and that monitoring should be linked with therapy. CPP-oriented protocols,[53] osmotherapy, and the Lund protocol[54] cannot be conducted correctly without guidance from real-time ICP recording. Similarly, a decision about performing a surgical intervention such as decompressive craniectomy should be supported by the close inspection of the trend of ICP and, preferably, by information derived from its waveform (see the previous discussion).

Newer modalities, however, may provide supplementary information about the state of the injured brain in a comatose patient. The role of these modalities is now

discussed, but first, by way of context, some consideration should be given to the mechanisms underlying brain injury.

Mechanism of Brain Injury Where Intracranial Hypertension Occurs

In patients with severe TBI, MRI commonly reveals focal lesions within the frontal and temporal lobes, the temporal poles, and the limbic system, including its connections with the orbitofrontal surface of the frontal cortex.[55,56] Pathologic change may occur by means of several injurious mechanisms in these regions. In the temporal lobes or its connections, manifestations of the following conditions may be found:

1. Direct high-speed impact injury with or without acceleration-deceleration forces. In this instance, the medial temporal lobe is vulnerable to mechanical deformation and contusion.[57]

2. Metabolic perturbation resulting from vascular or systemic factors such as hypoxia, ischemia, hypoglycemia, and seizures. In these head injury–related insults, there is a predilection for vulnerability within a structure in the temporal limbic system, the hippocampus.[58]

3. Diffuse axonal injury as a consequence of rotational forces at the time of injury affecting axonal integrity; thereafter, secondary or postacute deafferentation or deafferentation of structures such as the hippocampus occurs.[59,60]

4. Raised ICP with brain swelling resulting in pressure necrosis of the main cortical input to the hippocampus, to the parahippocampal gyrus, and against the free edge of the tentorium cerebelli.[61]

5. Frontal hemodynamic perfusion failure as a consequence of inadequate local CBF, failed local cerebral autoregulation, raised ICP, or anterior compartment syndrome (Fig. 66.11).

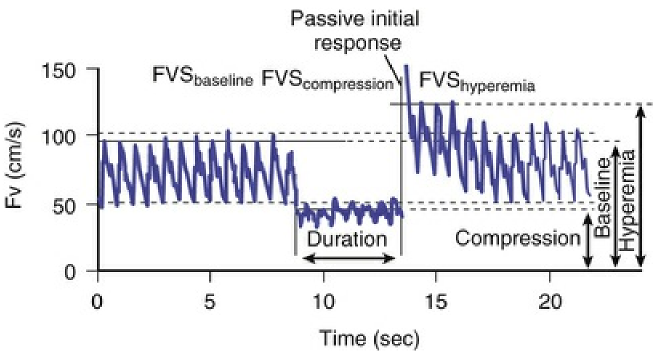

FIG. 66.11 Transient hyperemic response used test to assess autoregulation: middle cerebral artery blood flow velocity (Fv) is measured with transcranial Doppler ultrasonography before, during, and after a 6-second compression of the carotid artery. Hyperemia after release of compression signifies properly functioning vascular reactivity. *FVS*, flow

velocities.

When consideration is given to monitoring other modalities besides ICP, two problems are encountered. The first problem is understanding the extent to which these mechanisms contribute to the physiologic derangements that can be followed in the intensive care unit. The second problem is making a difference in patient assessment and outcomes, provided these mechanisms can be influenced.

Monitoring and the Postinsult Natural History

In a patient with severe TBI, the value and utility of monitoring may serve a spectrum of functions. Given the five potential mechanisms outlined in the previous section (ie, direct mechanical effect, metabolic perturbation, axonal injury, brain swelling, and hemodynamic perfusion failure), specific foci, whether for assessment or treatment, can be identified for monitoring. The potential for treatment rather than for assessment, however, will be limited by the time course over which the pathophysiologic monitoring is enacted. For example, the following need to be considered: What processes occur at the time of injury, what are the subsequent epiphenomena of these events, and what are the secondary factors that are amenable to treatment and altered outcome?[62-68] Mechanisms 1 and 3 occur at the time of injury, and mechanism 2 starts during the interval between the accident and arrival in the intensive care unit, although this mechanism may, in part, be avoidable with attention to emergency care and life support. Mechanisms 4 and 5 are processes in which treatment that is directed by intensive care monitoring presumably has the potential for altered outcome (ie, focal brain tissue shifts and hemodynamic perfusion failure). One important issue, therefore, is the natural history of brain swelling and local compartment syndrome after severe head injury. In persons with a TBI, intracranial hypertension occurs when there is brain swelling or a hematoma that occupies significant space. In persons with severe TBI and abnormalities shown with CT scans on admission, a greater than 50% chance of raised ICP exists. In adults, this complication may occur in persons whose CT scans appear normal, particularly if two of the following three features are present: age older than 40 years, unilateral or bilateral motor posturing, or systolic ABP below 90 mm Hg.

In children, the occurrence of this complication has been analyzed in a United Kingdom national dataset of all 501 children receiving critical care after sustaining a severe head injury. Forsyth and colleagues[69] found that by modeling demographic, acute physiologic, and cranial imaging variables they could derive an empiric decision rule that predicted the development of raised ICP at any point during intensive care unit admission with a sensitivity of 73% and a specificity of 74% (positive predictive value, 82%; negative predictive value, 63%). Overall raised ICP was present in 25% of those undergoing invasive monitoring. Importantly, the decision rule predicted raised ICP in 20% of children not undergoing ICP monitoring. Natale and associates[70] have shown that the natural history of raised ICP in children not requiring surgery after head injury can be as short as 3 days, but not infrequently it lasts for 7 to 10 days. Thus in regard to brain tissue shifts and frontal compartment perfusion failure, the potential of a postinsult “therapeutic window” exists, which also implies a goal for therapy directed by monitoring.

Newer Modalities Supplementing Monitoring of Intracranial Pressure

Many of the supplementary, often research-based modalities that are used in monitoring have only been tested in patients with severe TBI, because this is the most common reason for instituting ICP monitoring.

Brain Oxygenation

Jugular bulb oxygen saturation is commonly used to assess cerebral oxygenation. However, this form of monitoring has several shortcomings, not the least of which is that it is a global measure that is insensitive to small, though important, regional changes. The relatively recent development of implantable tissue oxygen and pH microsensors has meant that more direct regional assessments are now being made. The questions, though, are what is normal tissue oxygen tension, and what does it mean? Reports in adults indicate that the threshold for abnormality is around 10 mm Hg,[71,72] although the validity and appropriateness of using such an exact measure has been questioned by Gupta and colleagues.[73,74] These investigators used positron emission tomography scanning in 19 adults with head injuries to validate the reading of brain tissue oxygen pressure (P_tO_2) from a NeuroTrend sensor inserted into the frontal region. End-capillary oxygen tension (P_vO_2) was calculated from oxygen extraction fraction in a 20-mm region of interest around the sensor and compared with P_tO_2. No correlation was found between the absolute values of P_tO_2 and P_vO_2. In contrast, a significant correlation was obtained between the change in P_tO_2 and the change in P_vO_2 produced by a decrease in $PaCO_2$ by approximately 1 kPa (7.5 mm Hg). Therefore these authors could only conclude that such monitoring should be used to assess, in real time, the changes attributable to a particular intervention.

Ushewokunze and Sgouros[75] have reported on five children with head trauma for whom this monitoring has been used. In common with findings in adults, the low P_tO_2 levels that occur during the first 24 hours following severe TBI do not correlate necessarily with poor outcome, and an increase in ICP may be accompanied by a decrease in P_tO_2.

Microdialysis and Brain Tissue Biochemistry

Tissue biochemical metabolic markers—rather than serum or cerebrospinal biomarkers—can be assessed continuously using cerebral microdialysis; essentially, one is potentially sampling cerebral extracellular fluid and using changes to make inferences about cell homeostasis and perturbation. Currently, this approach is used predominantly for research purposes and in adult practice. The technology enables bedside measurement (usually hourly in the case of TBI) of levels of cerebral dialysate glucose, lactate, pyruvate, glutamate, and glycerol. Typically, the glucose level and lactate-pyruvate ratio (LPR) are used as indices of inadequate substrate delivery, altered metabolism, and ischemia. The use of a ratio (ie, LPR), rather than absolute concentrations, means that an alteration in dialysate recovery rate does not result in spurious changes in LPR. A ratio less than 20 suggests uncomplicated

cerebral metabolism,[76] and an increase in ratio is a sensitive indicator of a decrease in P_tO_2.[77] Dialysate increases in glutamate and glycerol are used as indices of cumulative tissue responses to secondary ischemic events such as intracranial hypertension, systemic hypotension, seizures, and contusions.

In adults with TBI, an increased ratio results from a 10-fold to 100-fold reduction in pyruvate concentration in association with a 2-fold to 5-fold increase in lactate concentration.[78] Two studies in adults with TBI, however, suggest that the LPR (and levels of the components that make up the ratio) might be revealing more about other forms of cerebral metabolic perturbation besides ischemic crisis. Hlatky and coworkers[79] found that in the first few hours after injury—at a time when P_tO_2 was normal (ie, nonischemic)—the LPR was increased because of low pyruvate concentration and not raised levels of lactate. Later when the P_tO_2 was at its lowest level, signifying "hypoxia/ischemia," increased LPR was due to a combination of increased lactate and decreased pyruvate levels. Vespa and associates[80] found that even though a raised lactate level or LPR was present in 25% of cerebral microdialysis samples, the occurrence of cerebral ischemia—defined as a raised lactate level, LPR, and a low glucose level—was much less frequent (~3%). Furthermore, upon combining these studies with positron emission tomography for assessing the metabolism of oxygen, the incidence of a high oxygen extraction fraction (ie, ischemia) was rare, at approximately 1%. Hillered and colleagues[81] have commented on these clinical reports in adults and suggested that the findings represent two metabolic states:

- *Type 1,* classical cerebral ischemia, is characterized by reduced microdialysis pyruvate and an increased level of lactate, leading to increased LPR (in association with depressed P_tO_2). This state is a result of an overt lack of oxygen and glucose at the mitochondria.
- *Type 2,* cerebral metabolic perturbation, occurs when P_tO_2 is normal (ie, nonischemic) and a reduction in pyruvate is the sole change in dialysis metabolites. The rise in LPR in this state is "perhaps reflecting a limited glucose supply or an impairment of the glycolytic pathway."

However, the mechanism of these early type 1 and type 2 changes are not fully understood, and there is an important difference between the study by Hlatky and coworkers[79] and that reported by Vespa and associates[78,80]: In the first study the microdialysis probes were placed perilesional or pericontusional; in the second study the microdialysis probes were cited as being placed in the nondominant, normal-appearing frontal lobe tissue. This difference is likely to be significant because, as Engstrom and colleagues[82] reported, microdialysis monitoring of normal-appearing tissue is not representative of perilesional tissue. Raised LPR persisted for at least 72 hours in perilesional tissue. In the first 36 hours this rise was associated with raised lactate levels and raised pyruvate concentrations. After that time, raised LPR was a reflection of raised lactate levels with normal pyruvate concentrations. All microdialysis parameters were in the normal range in normal-appearing tissue. These observations suggest that perilesional tissue has features of type 1 cerebral metabolic crisis, but the absence of depressed P_tO_2 suggests that increased lactate occurs as a consequence of increased glycolytic activity, which may be due to perilesional depolarizations.[83] Such hyperglycolysis is marked by increased

metabolism relative to utilization and, after trauma, it represents an uncoupling between predominantly glycolytic and oxidative metabolism.[84]

In the broader context of managing intracranial hypertension, one needs to consider whether microdialysis and monitoring brain tissue biochemistry will have a role beyond the physiologic insights previously described. For example, if measurements are made hourly—dialysate flow rate of 0.3 μL/min is the most common—then what does a change represent: a concurrent acute event, a prolonged ongoing event, or an acute event that has now resolved but with abnormal tissue biochemistry? Belli and associates[85] addressed this issue by examining whether metabolic impairments preceded rises in ICP. The authors found that an abnormal LPR could predict an ICP rise in 89% of cases. An LPR above 25 was associated with an odds ratio of 9.8 (95% CI, 5.8 to 16.1) of imminent intracranial hypertension. With regard to the utility of this form of monitoring in children, we know that in the United Kingdom national dataset of critical care for severe TBI, less than 1% of children undergo such monitoring.[86] To date, a case series of only nine children has been reported.[87,88]

Taking all of this metabolic information together, it is unclear whether the real-time cerebral microdialysis data have the potential to direct or influence our practice of ICP/CPP control. What is more intriguing, however, are the reports that indicate how such monitoring can be used to integrate what fuel the distressed brain needs[89,90] and thereby mitigate the severity of ICP/CPP levels.

Transcranial Doppler and Assessment of Autoregulation

TCD ultrasonography provides noninvasive measurement of blood flow velocity in basal cerebral arteries.[22] Most data have been derived from the MCA. This vessel is readily accessible to the ultrasonographer; it is the most convenient for probe fixation and long-term monitoring, and it delivers the largest percentage of supratentorial blood. Although the blood flow velocity cannot express a baseline volume of flow, dynamic changes of CBF are usually reflected in the TCD readings.[22,91] The response of blood flow velocity to a critical decrease in CPP is sensitive and usually immediate (see Fig. 66.11). It is this high-dynamic resolution and close correlation with other hemodynamic modalities that has encouraged the development of the technique in clinical practice.

Increased baseline flow velocity (>100 cm/sec) may indicate cerebral vasospasm or hyperemia.[92,93] Uncoupling between CBF and flow velocity in vasospasm has been documented both experimentally and clinically.[94] For example, if the ratio of flow velocity in the insonated artery to the velocity in the ipsilateral internal carotid artery is greater than 3, vasospasm is likely. A ratio lower than 2 indicates hyperemia as the cause for accelerated blood flow.[95] After a severe TBI is sustained, cerebral autoregulation is frequently disturbed, although the extent of this disturbance may fluctuate with time.[8,9] In a prospective, observational study of 69 children with TBI (GCS score ≤12) and abnormal head imaging, O'Brien and colleagues[96] undertook TCD studies to identify and follow vasospasm. The prevalence of MCA vasospasm with moderate TBI (GCS 9-12) was 8.5%, and it was 33.5% in those with severe TBI (GCS ≤8). Mean time to onset of vasospasm was 4 days and the mean duration of vasospasm was 2 days. Children in whom vasospasm developed were more likely to have been involved in motor vehicle accidents, had higher Injury Severity scores,

had fever at admission, and had lower GCS scores.

At present, few pediatric practitioners in critical care medicine are credentialed to undertake TCD for clinical care. This specialization may change in the future as we adopt more adult neurocritical care training requirements. For example, in adult practice it is interesting to note the range of assessments that can be conducted at the bedside:

1. *Static test of autoregulation.* Methods for the static assessment of autoregulation rely on measurement of MCA blood flow velocity during changes in mean ABP induced by a vasopressor infusion. The static rate of autoregulation (SoR) can be calculated as the percentage increase in vascular resistance divided by the percentage rise in ABP. An SoR of 100% indicates fully intact autoregulation, whereas an SoR of 0% indicates fully depleted autoregulation.

2. *TCD reactivity to changes in carbon dioxide concentration.* Testing for CO_2 cerebrovascular reactivity has been shown to have an important application in the assessment of severe head injuries and other cerebrovascular conditions. Many authors have shown that cerebral vessels are reactive to changes in CO_2 when cerebral autoregulation had been impaired.[97] CO_2 reactivity correlates significantly with outcome after a head injury. In patients with an exhausted cerebral compensatory reserve, however, hypercapnia may provoke substantial changes in ICP. Therefore this method cannot be used without consideration of patient safety, particularly if baseline ICP is already elevated.

3. *Dynamic test of autoregulation.* Aaslid and colleagues[98] described a method in which a step decrease in ABP is achieved by the deflation of compressed leg cuffs while TCD flow velocity in the MCA is simultaneously monitored. An index called the dynamic rate of autoregulation describes how quickly cerebral vessels react to the sudden fall in blood pressure. The dynamic rate of autoregulation is thought to express the autoregulatory reserve and, in adult volunteers, has been shown to correlate with blood CO_2 concentration in volunteers.[99]

4. *Transient hyperemic response test.* Short-term compression of the common carotid artery produces a marked decrease in MCA blood flow velocity in the ipsilateral hemisphere. During compression, the distal cerebrovascular bed dilates if autoregulation is intact. On release of the compression, transient hyperemia, which lasts for a few seconds, occurs until the distal cerebrovascular bed constricts to its former diameter. This sequence of events, which underlies the transient hyperemic response test, indicates a positive autoregulatory response (see Fig. 66.11). In persons with a head injury, preliminary results show a positive correlation between the presence of a hyperemic response and outcome.[100]

5. *Continuous analysis of TCD ultrasonography with respiratory waves.* An interesting method of deriving the autoregulatory status from natural fluctuations in MCA blood flow velocity involves the assessment of phase shift between the superimposed respiratory and ABP waves during deep breathing.[101] A 0-degree phase shift indicates absent autoregulation, whereas a phase shift of 90 degrees indicates intact autoregulation. Such an approach may allow for the continuous

assessment of autoregulation without performing potentially hazardous test maneuvers on arterial pressure.

6. *Continuous analysis of TCD flow velocity waveform.* In patients with severe head injuries, CPP monitoring can be correlated with mean blood flow velocity continuously. For example, consecutive CPP samples (averaged over 5-second periods) can be assessed with average flow velocity (collected over 5-minute epochs). The correlation coefficient (named mean index) may be positive or negative, and the regression line describing the relationship between the systolic-, mean-, and diastolic-flow velocity and the CPP may be used for assessment. A positive correlation coefficient signifies a positive association of flow velocity with CPP; a negative correlation coefficient signifies a negative association. In persons with a head injury, group analysis has shown that clinical outcome depends on the averaged autoregulation indices.[9] Furthermore, time analysis has shown that failure of autoregulation is a strong independent predictor of fatal outcome after a head injury.[102]

Some data on TCD assessments of cerebral autoregulation in children with TBI are now available. For example, in a series of 36 children, the incidence of impaired cerebral autoregulation was greatest following moderate to severe TBI.[103] Impaired autoregulation was associated with poor outcome, and hyperemia was associated with both impaired autoregulation and poor outcome. In severe cases, cerebral autoregulation often changes over the course of a critical illness, with worsening autoregulation mirroring progression of worsening injury.[104] Importantly, in children, bilateral assessment of cerebral autoregulation is required because hemisphere differences are common in those with an isolated focal injury.[105] Finally, inflicted TBI probably should be considered a special case: In a small case series, Vavilala and coworkers[106] found that none of their critically ill cases had intact autoregulation.

CHAPTER 67

Status Epilepticus

Edward E. Conway Jr.

PEARLS

- A seizure is a paroxysmal central nervous system disorder resulting from excessive hypersynchronous discharge of cortical neurons.
- Status epilepticus is a common pediatric neurologic emergency and requires rapid recognition and intervention.
- An operational definition of status epilepticus recommends administration of an antiepileptic agent (AED) after 5 minutes of seizure activity, and a predetermined pathway/guideline can expedite management.
- Management goals include general supportive care, termination of status epilepticus, prevention of recurrence, correction of precipitating causes, and prevention and treatment of potential complications.
- Common errors include underdosing the initial AED and delay in advancing to a second-line AED. A single drug should be maximized to a high therapeutic or supratherapeutic level before adding a second or third drug.
- The longer seizures continue, the more difficult they are to abort with medications. Early diagnosis and aggressive intervention for both convulsive and nonconvulsive seizures are essential for successful treatment.
- Prolonged seizures may cause selective neuronal loss in the hippocampus, cortex, and thalamus, areas rich in glutamate receptors.

A seizure is a paroxysmal disorder of the central nervous system (gray matter) characterized by an abnormal neuronal discharge associated with a change in function of the patient. It results from the excessive hypersynchronous discharge of cortical neurons in the gray matter.

Factors that occur commonly in the pediatric intensive care unit (PICU) and are known to provoke seizures include fever, hyponatremia, hypoglycemia, hypocalcemia, meningitis, head trauma (accidental or nonaccidental), toxin exposure, ethanol, and many other drugs (both legal and illicit). Seizures are a common pediatric entity and occur in almost 5% to 8% of pediatric-aged patients with the highest risk occurring during infancy and early childhood. A seizure must be differentiated from other paroxysmal events, which may include syncope, breath-holding spells, movement disorders, or hyperventilation syndrome.

Status epilepticus (SE) is a common pediatric neurologic emergency estimated to affect between 25,000 to 50,000 children annually, and 40% of all instances of SE will occur in children under age 2. The incidence of convulsive SE in children is approximately 10 to 27/100,000 per year. The definition of SE has undergone revisions, and it was previously defined as a seizure lasting for greater than 30 minutes or recurrent seizures lasting for more than 30 minutes without the patient regaining consciousness between seizures. No clinical data support the 30-minute rule, however, and more recent definitions of SE include a shorter duration of seizure activity. The early definitions were based on animal studies, which suggested that neuronal damage would occur if seizures persisted beyond an established timeline. Much has been learned since these early studies, and it appears that it is the underlying disorder that causes the morbidity and mortality seen in SE. The majority of tonic-clonic generalized seizures will self-terminate in less than 5 minutes.[1] The goal of treating prolonged seizures is to prevent morbidity and mortality, and a new operational definition of SE has been proposed: Generalized convulsive status epilepticus in adults and older children (>5 years old) refers to ≥5 minutes of (1) continuous seizure or (2) two or more discrete seizures between which there is incomplete recovery of consciousness.[2,3]

The authors of this new definition cite a paucity of pediatric data to make recommendations in children younger than 5 years. Although there is general agreement that seizures continuing for longer than 5 minutes should be treated, there exists a concern that overaggressive treatment may lead to avoidable morbidity. A study by DeLorenzo (which included 91 children) compared the outcome of patients with seizures lasting 10 to 29 minutes with that of traditionally defined SE (>30 minutes).[1] Almost 50% of the seizures in the 10- to 29-minute group stopped spontaneously (without therapy), and this group had no mortality. In comparison, the other 50% of patients in the 10- to 29-minute group, who required therapy to stop the seizures, had a mortality of 4.4%. The traditional group (seizures lasting >30 minutes) had a mortality of 19%.[1] Children with SE have an overall mortality of approximately 0% to 3%. Apart from mortality, SE survivors also have an increased risk of subsequent epilepsy, reported to be between 13% and 74%.[4] SE recurs in approximately 20% of cases within 4 years of initial presentation, with most recurrences occurring during the first 2 years.[4] Seizures and SE recurrence are influenced by the underlying etiology, with structural or metabolic lesions associated with the highest risk.[4] Regardless of the definition of SE, there is a consensus in the medical community that continuous or prolonged seizures require urgent intervention. Children with prolonged seizures should receive prompt and aggressive treatment with the aim of stopping seizures as soon as possible.

Two large case series demonstrated similar results showing that SE accounted for 1.6% and 2% of total admissions to the PICU.[5] Although this represented a small total number of patients admitted to the PICU, there was morbidity and mortality associated with SE. SE occurs more frequently in infants and children than adults; the overall mortality is much lower at 3.6%.[5]

SE also may be classified with respect to cause. *Symptomatic* implies a known cause for SE (structural or metabolic) and can be further divided into acute symptomatic and remote symptomatic. Acute symptomatic seizures are those occurring in close temporal association (<7 days) to an acute systemic metabolic or toxic insult or in association with an acute CNS insult. Remote symptomatic refers to seizures owing

to a remote CNS injury (>1 week) such as infection, trauma cerebrovascular disease, or cortical dysgenesis, which are presumed to result in a static lesion. Remote symptomatic SE is most often associated with a long-standing history of epilepsy or remote central nervous system (CNS) insult. The term *idiopathic SE* is used when there is no known or suspected cause for the seizures (Fig. 67.1).[6]

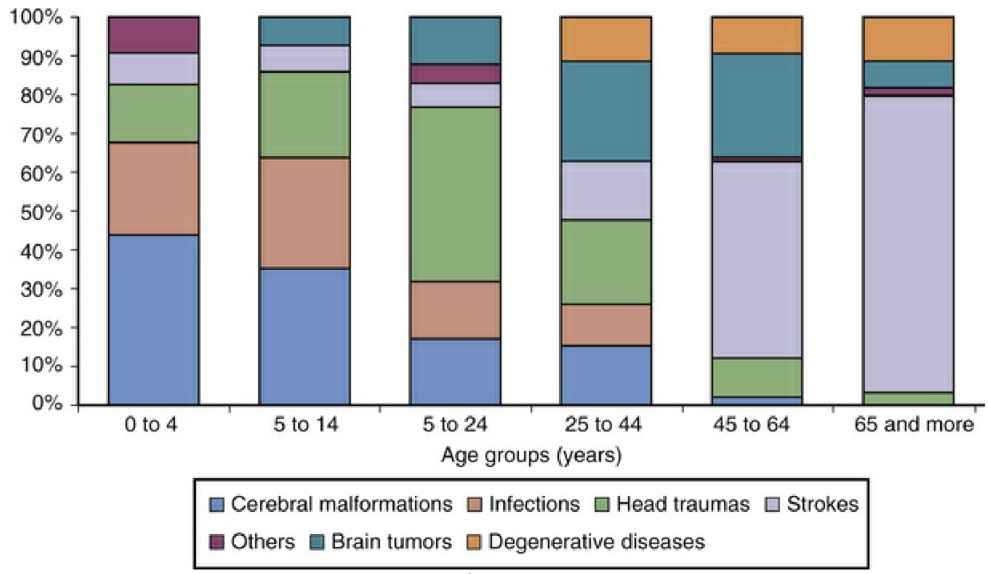

FIG. 67.1 Proportional incidences for symptomatic epilepsies according to age and etiologies. (From Major P, Thiele EA. Seizures in children: determining the variation. Pediatr Rev. 2007;28:363-371.)

Proportional Incidences for Symptomatic Epilepsies According to Age and Etiology

The most common causes of SE reported in pediatric patients include an underlying seizure disorder, fever, meningitis, and encephalitis. One of the largest series of SE in children was published in 1970. This review of 239 cases of SE in children identified 47% of cases to be symptomatic (26% acute symptomatic and 21% remote symptomatic) and the remaining 53% of cases to be idiopathic, including febrile SE.[7] The cause of SE is age dependent; infection plays a larger role in the cause of SE in children than in adults. In a 1996 study in Richmond, Virginia, the three major causes of SE in children were infection with fever, remote symptomatic cause, and low anticonvulsant drug levels (Table 67.1).[8] Three major causes in adults were low antiepileptic drug (AED) levels, remote symptomatic cause, and stroke.[8] The cause also differs among younger and older children. Febrile and acute symptomatic SE are more common in children younger than 2 years, whereas idiopathic and remote symptomatic causes are most common in children older than 4 years.[9,10] In children with a first seizure, 12% present in SE.[11] In a report of 613 children with newly diagnosed epilepsy, 9.1% had provoked or unprovoked SE before the diagnosis of epilepsy and a nearly equal number, 9.5%, had an episode of SE following the diagnosis of epilepsy (8-year median follow-up).[12,13] Children who had SE before a

diagnosis of epilepsy were most likely to have remote symptomatic epilepsy. Younger age of epilepsy onset and symptomatic epilepsy increased the risk of SE.[14]

TABLE 67.1

Physiologic Derangements in Status Epilepticus

	Early <30 min	Late >30 min	Complication
Blood pressure	↑	↓	Hypotension
Pao_2	↓	↓	Hypoxia
$Paco_2$	↑	Variable	↑ Intracranial pressure
Serum pH	↓	↓	Acidosis
Automatic	↑	↔	Arrhythmias
Creatine kinase	Normal	↑	Renal failure
Potassium	Normal	↑	Arrhythmias
Cerebral blood flow	↑ 900%	↑ 200%	Central nervous system bleed
Cerbral metabolic rate of oxygen consumption	↑ 300%	↑ 300%	Ischemia

Modified from Dean JM, Singer HS. Status epilepticus. In: Rogers MC, ed. Textbook of Pediatric Intensive Care Medicine. Baltimore: Williams & Wilkins; 1987:618.

Epilepsy is a chronic seizure disorder characterized by recurrent (more than two) unprovoked seizures usually in a person who has a predisposition because of an underlying state. It is also a potential long-term complication of SE, refractory status epilepticus (RSE) cEEG, and super-refractory status epilepticus (SRSE).

Refractory SE is defined as continued SE despite the administration of multiple first- and second-line agents with different mechanisms of action including benzodiazepines, fosphenytoin or phenytoin, and phenobarbital. Often these patients have had continuous (clinical or electrographical) seizure activity for hours. The care of these patients should be a collaborative effort between intensive care specialists and neurologists and requires standard invasive intensive care monitoring as well as the 24-hour availability of electroencephalography (EEG). Treatment of refractory status epilepticus requires continuous EEG (cEEG) monitoring because pharmacologic therapy is titrated to EEG seizure suppression or burst suppression. Mortality rates for RSE are as high as 30%.[14]

Super-refractory SE is defined as SE that continues 24 hours or more after the onset of anesthetic therapy for SE, including those cases in which SE recurs during reduction or withdrawal of anesthesia.[14]

Nonconvulsive status epilepticus (NCSE) is defined as clinically subtle or nonconvulsive seizures, which may be common among patients in the intensive care unit, particularly following prolonged convulsive seizures. Postictal stupor or coma due to the sedative effects of medications is often difficult to distinguish from continued nonconvulsive seizures without the aid of cEEG monitoring. Electrographic seizure activity has been reported to occur in up to 15% of patients whose overt clinical seizures are pharmacologically controlled.[12,15,16]

Seizures and SE may occur as common complications in medical and surgical patients in the PICU without an underlying neurologic disorder (Box 67.1).

Box 67.1

Common Causes of Seizures in the Pediatric Intensive Care Unit

Stroke/arteriovenous malformation/hemorrhage	Hypoxia and ischemia
Tumor	Fever and febrile seizures
Meningitis/encephalitis/abscess	Drug toxicity and withdrawal
Vasculitis	Renal/hepatic dysfunction
Traumatic brain injury	Metabolic: ↑↓ glucose
Preexisting epilepsy	↑↓ Sodium
Antiepileptic agent withdrawal or change	↑↓ Calcium
Postoperative craniotomy	↑↓ Serum osmol
Genetic CNS disorders	Hypertensive encephalopathy
Cerebral malformation	Neurocutaneous syndromes

Seizure Types and Classification

Seizures are classified based on the clinical presentation and electroencephalographic patterns and are simply divided into partial or generalized seizures. Partial seizures (also referred to as simple, local, or focal) arise in specific areas of the brain, and their presentation depends on the primary function of the affected area (motor, sensory, visual, auditory, gustatory, or affective). Simple partial seizures may remain focal or they can become complex (implying loss of consciousness) and further evolve into a generalized tonic-clonic seizure.

The second group of seizures refers to those labeled as generalized (thus implying that the seizures arise from diffuse cortical areas at one time). Generalized seizures refer to seizures involving both cerebral hemispheres, which are believed to originate within, and rapidly engage, bilaterally distributed neuronal networks. Consciousness is usually impaired. Generalized seizures include seizures with motor movements as well as absence seizures during which no convulsive signs may be present. EEG indicates seizure activity involving both cerebral hemispheres.

Febrile seizures (FSs) are the most common type of pediatric seizure and occur in patients between 6 months and 5 years of age associated with fever but without intracranial infection or defined cause. They are usually transient, age-related responses to noxious stimuli. They occur at a peak incidence of about 18 months and are generalized tonic-clonic and last less than 10 minutes followed by a brief postictal period. Factors associated with the risk of having an FS include a family history of FS, peak temperature, and the nature of the underlying illness. The mean temperature associated with FS is approximately 39°C or greater, and it appears that it is the peak temperature not the rising phase of the fever that is relevant. Studies suggest that cytokines such as interleukin-1, which is a proconvulsant agent, may play a role in febrile seizures. Febrile seizures are classified as simple or complex. FSs are considered simple when they are generalized, do not recur within a defined illness, and last less than 10 to 15 minutes. Complex febrile seizures are defined as those that are focal, last longer than 10 to 15 minutes, or occur multiple times within the same febrile illness.[17-20]

Febrile Status Epilepticus

Approximately 5% of children who present with an FS will have an episode of FSE. Although only a small number of children with an FS will develop SE, this accounts for almost 25% of cases of pediatric SE. Febrile status epilepticus (FSE) rarely stops spontaneously, is fairly resistant to medications, and even with proper treatment may persist for a significant period of time. The FEBSTAT study reported on 199

subjects with FSE with a mean seizure duration of 81 minutes for subjects receiving medications prior to arriving at the emergency department (ED); the median time from the first dose of an AED to the end of the seizure was 38 minutes, and the initial dose of lorazepam or diazepam was suboptimal in 19% of patients (34/166).[17-20]

Seizures Commonly Encountered in the Pediatric Intensive Care Unit

Chemically Induced Seizures

It is difficult at times to determine the immediate precipitant of a seizure/SE in critically ill patients, as multiple factors that can lower the seizure threshold include the underlying medical or surgical process, medications, renal or hepatic dysfunction or failure, fever, hypoxia, metabolic abnormalities, or alkalosis. Medications commonly associated with a decreased seizure threshold include antidepressants, antibiotics, analgesics, antiarrhythmics, baclofen, chemotherapeutic agents, drug withdrawal (barbiturates, alcohol, opiates), immunomodulators (cyclosporine, tacrolimus, interferons), lithium, neuroleptics, radiographic contrast agents, and theophylline. Drugs of abuse associated with seizures/SE include cocaine, amphetamines, phencyclidine, and gamma-hydroxybutyric acid. Less common causes include carbon monoxide, lead, envenomations, camphor, iron, and organophosphates.

Dialysis Disequilibrium Syndrome

Dialysis disequilibrium syndrome is characterized by neurologic symptoms (headache, nausea, disorientation, restlessness, blurred vision, asterixis, confusion, seizures, coma, and even death) seen during or immediately after hemodialysis. The pathophysiology is thought to involve the movement of water into the brain causing cerebral edema following the rapid removal of urea, which lowers the plasma osmolality causing a transient osmotic gradient that favors movement of water into the brain.

Hepatic Mechanisms

Hepatic postulated mechanisms of seizures in liver failure include hyperammonemia, abnormal glutamine metabolism, cerebral ischemia, cerebral edema, accumulation of toxins, or associated electrolyte abnormalities such as hyponatremia, hypomagnesemia, or elevated blood urea nitrogen or creatinine. The management of these seizures and possible SE is the same as in other conditions except one must be cautious with the selection of an antiepileptic medication that is cleared by the liver. The degree of hepatic failure may influence the metabolism of an AED, as early in the process there may be increased blood flow to the liver with normal function where the AED may be normally cleared; however, in the later stages of hepatic failure with necrosis and loss of hepatic cellular function, the AED may not be cleared, leading to a potentially toxic AED level. Hypoalbuminemia may also contribute to AED toxicity, particularly in highly protein-bound drugs such as phenytoin and valproic acid.

Hypertensive Encephalopathy

Patients with hypertensive encephalopathy have disordered cerebral autoregulation and may develop what has been termed *posterior reversible encephalopathy syndrome (PRES).* Presenting signs and symptoms include headache, visual complaints, vomiting, and seizures. Cerebral autoregulation is the process by which cerebral blood flow (CBF) remains constant across a wide range of cerebral perfusion pressures (CPPs). As the mean arterial pressure (MAP) exceeds 150 to 160 mm Hg, arteriolar vasoconstriction is exhausted and hydrostatic pressure increases continuously resulting in a breakdown of the blood-brain barrier producing cerebral edema (see also Chapters 60 and 66). The increased incidence of vasogenic edema in the parietal and occipital lobes is thought to be due to poor sympathetic innervation of the posterior circulation of the brain.[21,22]

Neonatal Seizures

Neonatal seizures occur secondary to acute brain insults such as vascular, infectious, metabolic, or toxic etiologies during the first 28 days of life. The most common cause is hypoxic-ischemic injury (60%-70%), followed by hemorrhage (~10%), and the remaining causes include sepsis, metabolic disorders, meningitis, hypoglycemia, hypo- and hypernatremia, and hypocalcemia. The incidence is between 1.5 and 5.5/1000 neonates.[23]

Animal data support the concept that newborns are more susceptible to seizures due to excitatory processes developing before inhibitory ones, differences in the microenvironment, and a higher incidence of being exposed to potentially epileptogenic stimuli (hypoxia, fever, infection). Most neonatal seizures occur within the first week of life, and the incidence is highest in low-birth-weight babies. Because the newborn brain is undergoing tremendous growth (it will double in size in 6 months) and there is incomplete development of dendrites, axons, and a lack of myelination, classic generalized tonic-clonic seizures seen in older pediatric patients may not be observed. Neonatal seizures may be subtle and include facial or extremity twitching, posturing, eye deviations, muscle jerking of the extremities, chewing, blinking, bicycling, and apnea. Other autonomic changes that may be seen include hypertension and tachycardia.[23-25]

Posttraumatic Epilepsy

Posttraumatic seizures occur in roughly 25% to 30% of pediatric victims of moderate or severe traumatic brain injury (TBI) and are associated with adverse outcome (see also Chapter 119). The occurrence of posttraumatic seizures or epilepsy increases with injury severity, younger age, and longer follow-up duration. Seizures seen in patients with severe TBI are frequently refractory to medical therapy. Posttraumatic epileptogenesis is a multifactorial process and may involve changes in excitatory and inhibitory networks, altered calcium-mediated second messenger activity, changes in ionotropic receptor function and composition, altered endogenous neuroprotectant activity, or TBI-induced cortical dysplasia.[26-28]

Renal Failure

Acute renal failure is associated with a uremic encephalopathy and seizures that may result from metabolic abnormalities including hyponatremia, calcium disorders, uremia, and hypertensive encephalopathy or disequilibrium syndrome seen with hemodialysis. Treatment of seizures in these patients can be difficult as a result of AED pharmacokinetics in uremia, decreased albumin, and dialysis effects. AEDs that are tightly protein bound (phenytoin, valproic acid) are not significantly dialyzed and usually do not need to be replaced. One should be cautious, however, as the unbound portion of drug may be higher and dosing adjustments may be necessary.

Transplantation

Solid organ transplant is frequently complicated by a spectrum of seizure types, including single partial-onset or generalized tonic-clonic seizures, acute repetitive seizures, or status epilepticus. Seizures may be seen frequently in transplant patients and may result from hyponatremia, hyper/hypoglycemia, immunosuppressive agents, high-dose antibiotics, infections, cerebral edema, infarction, or post-anoxic encephalopathy following hypotension or sepsis. Most seizures occur in the postoperative period on days 4 to 6. The immunosuppressive agents most frequently implicated are the calcineurin inhibitors cyclosporine and tacrolimus. Medication interactions have been described, as phenytoin decreases absorption of cyclosporine, and enzyme inducers (phenytoin, phenobarbital) may increase the clearance of cyclosporine and methylprednisolone.[29]

Pediatric hematopoietic cell transplant (HSCT) is associated with a large spectrum of complications. The most frequent complications are CNS infections, cerebrovascular or metabolic events, and neurotoxicity of immunosuppressive agents manifesting as PRES. Seizures are reported in 7% to 12% of transplanted patients and in 53% to 75% of patients with neurologic complications. There is currently no specific evidence involving the transplant patient population to guide the selection, administration, or duration of AED treatment.[30]

Autoimmune Status Epilepticus

Autoimmune SE is a rare condition but one that has been increasingly recognized by neurologists and PICU physicians. SE may be considered autoimmune if it is refractory to AED treatment and there is no other known cause; this may then lead to empiric immunomodulatory therapy. Major factors that raise the index of suspicion are recent cognitive or behavioral alterations, a history of malignancy or tumor, or the presence of other neurologic features. Treatment may include immunotherapy such as corticosteroids, IV immunoglobulin, plasmapheresis, and other immunosuppressive agents while attempting to maximize AED therapy.[31-33]

Neurophysiology

Seizures result from abnormal synchronous electrical discharge (depolarization) of a group of neurons in the CNS. Depolarization results from the influx of sodium into the neuron, whereas repolarization results from the egress of potassium from the cell resulting in the restoration of the resting negative electrical potential across the cell. This potential is regulated by a sodium-potassium pump that is ATP driven.

Figs. 67.2 and 67.3 provide an excellent overview of the physiology of a normal neuron and the pathophysiology associated with seizures, and the reader is referred to the article by Stafstrom.[34] The ineffective recruitment of inhibitory neurons coupled with excessive neuronal stimulation is a key participant in the initiation and propagation of the electrical disturbance occurring in SE. γ-Aminobutyric acid (GABA) is the major inhibitory neurotransmitter in the CNS. GABA receptors have a chloride ion channel complex and binding sites for barbiturates and benzodiazepines. Activation of these receptors allows for an inward movement of Cl^-, which restores the negative resting potential to the neuron to prevent further firing. The use of GABA agonists and the resultant suppression of seizure activity supports the perception that GABA plays a role in the normal termination of a seizure.

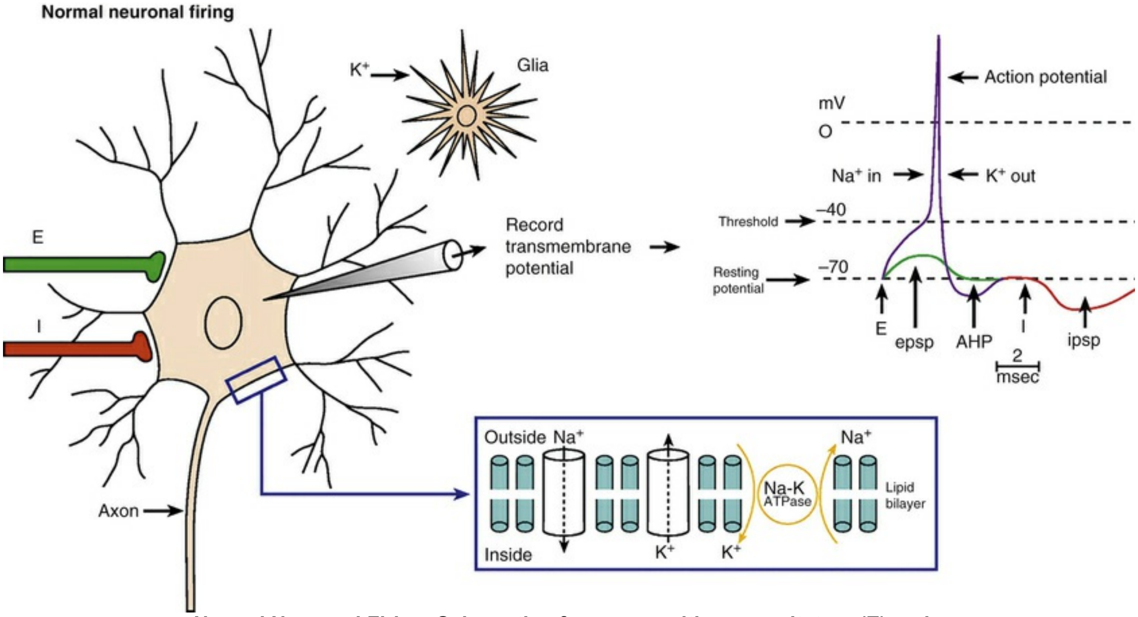

FIG. 67.2 Normal Neuronal Firing. Schematic of a neuron with one excitatory (E) and one inhibitory (I) input. Right side shows membrane potential (in mV), beginning at resting potential (−70 mV). Activation of E leads to graded excitatory postsynaptic potentials, the larger of which reaches threshold (about −40 mV) for an action potential. The action potential is followed by an after hyperpolarization (AHP), the magnitude and duration of which determine when the next action potential can occur. Activation of I causes an inhibitory postsynaptic potential. Inset shows a magnified portion of the neuronal membrane as a lipid bilayer with interposed voltage-gated Na^+ and K^+ channels; the direction of ion fluxes during excitation is shown. After firing, the membrane-bound Na-K pump and star-shaped astroglial cells restore ionic balance. (Reprinted with permission. Stafstrom CE. The pathophysiology of epileptic seizures: a primer for pediatricians. Pediatr Rev. 1998;19:342-351.)

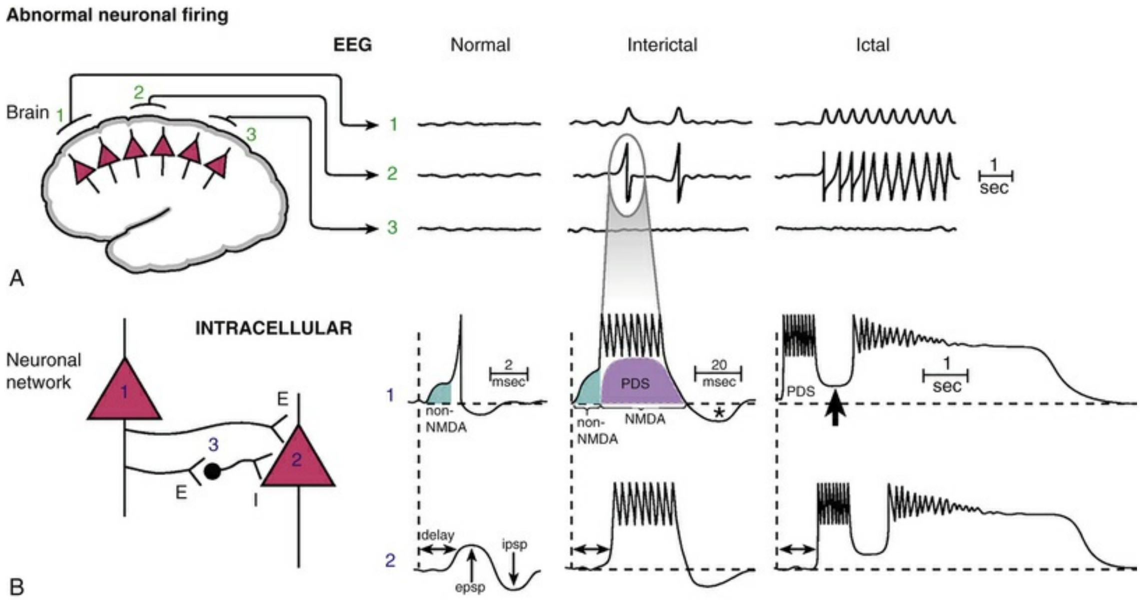

FIG. 67.3 **Abnormal Neuronal Firing. Abnormal neuronal firing at the levels of (A) the brain and (B) a simplified neuronal network, consisting of two excitatory neurons (1 and 2) and an inhibitory interneuron (3). EEG *(top set of traces)* and intracellular recordings *(bottom set of traces)* are shown for the normal *(left column)*, interictal *(middle column)*, and ictal conditions *(right column)*. Numbered traces refer to like numbered recording sites. Note time scale differences in different traces. (A) Brain. Three EEG electrodes record activity from superficial neocortical neurons. In the normal case, activity is low voltage and *desynchronized* (neurons are not firing together in synchrony). In the interictal condition, large spikes are seen focally at electrode 2 (and to a lesser extent at electrode 1, where they might be termed *sharp waves*), representing synchronized firing of a large population of hyperexcitable neurons (expanded in time below). The ictal state is characterized by a long run of spikes. (B) Neuronal network. At the neuronal network level, the intracellular correlate of the interictal EEG spike is called the *paroxysmal depolarization shift (PDS)*. The PDS is initiated by a non-NMDA–mediated fast excitatory postsynaptic potential (EPSP) but is maintained by a longer, larger NMDA-mediated EPSP. The post-PDS hyperpolarization (*) temporarily stabilizes the neuron. If this post-PDS hyperpolarization fails *(right column, thick arrow)*, ictal discharge can occur. The lowermost traces, recordings from neuron 2, show activity similar to that recorded in neuron 1, with some delay *(double-headed arrow)*. Activation of inhibitory neuron 3 by firing of neuron 1 prevents neuron 2 from generating an action potential (the inhibitory postsynaptic potential [IPSP] counters the depolarization caused by the EPSP). If it does not reach firing threshold, neuron 2 can then recruit additional neurons, leading to an entire network firing in synchrony (seizure).** (Reprinted with permission. Stafstrom CE. The pathophysiology of epileptic seizures: a primer for pediatricians. Pediatr Rev. 1998;19:342-351.)

Glutamate is the excitatory neurotransmitter of the CNS and has been implicated in the propagation of seizures by its effects on the *N*-methyl-D-aspartate (NMDA) and non-NMDA channels and via secondary messenger systems (metabotropic) receptors.[35] The NMDA receptor may have a dual function in the pathophysiology of SE. Magnesium blocks the NMDA channel when it is in its normal state. With depolarization, magnesium no longer blocks the channel, and calcium, which is allowed to flow into the cell, produces further depolarization. Thus the NMDA receptor is activated when the cell is depolarized and responds by further depolarizing the cell, sustaining the excitation.[35,36] Glutamate agonists produce seizures and glutamate antagonists inhibit seizures. The continued and unabated stimulation of neurons by glutamate ultimately leads to neuronal cell failure and increased levels of intracellular calcium, which contribute to neuronal injury in SE patients. Calcium activates proteases and lipases that degrade intracellular elements, leading to mitochondrial dysfunction and cellular necrosis. The longer that SE continues, the harder it becomes to stop the seizure pharmacologically. This may be due to a shift from inadequate GABAergic inhibitory activity to excessive NMDA

excitation.

Prolonged seizures have been associated with deficits in GABA-mediated neuronal inhibition because of the rapid internalization of synaptic $GABA_A$ receptors. Clinically this phenomenon may be demonstrated by the poor response of prolonged seizures to the GABA agonist's benzodiazepines and barbiturates,[37] a phenomenon known as time-dependent pharmacoresistance.[38-40]

Prolonged seizures may cause selective neuronal loss in the hippocampus, cortex, and thalamus, areas rich in glutamate receptors. This calcium-mediated neuronal cell death is referred to as the *excitotoxic theory,* which is similar to that proposed to occur in CNS ischemia. Studies looking at markers of neuronal injury (neuron-specific enolase) have shown elevations following prolonged convulsive and nonconvulsive SE. Although prolonged seizures may be sufficient to cause neuronal damage, the superimposition of hypoxia, hypotension, acidosis, and hyperpyrexia exacerbate the degree of damage.

SE may be divided into two stages, with the first 30 minutes characterized by increased autonomic activity including hypertension, tachycardia, hyperglycemia, diaphoresis, and hyperpyrexia. This is followed by a transition period after approximately 30 minutes when patients enter a second phase, which is characterized by multiorgan involvement and includes respiratory failure (hypoxemia, hypercarbia), decreased CBF, increased intracranial pressure (ICP), and a dropping arterial blood pressure. Severe acidosis ensues and the patients may develop rhabdomyolysis with a leukocytosis, hyperkalemia, and an elevated creatine kinase (secondary to increased muscle activity). These findings are summarized in Table 67.1.

Early in SE, an increase in neuronal metabolic demand occurs with a compensatory increase in CBF and brain oxygenation. Later in SE, these homeostatic mechanisms are unable to keep up with the sustained increase in cerebral metabolic demand. Autoregulation of CBF fails, and consequently a higher mean arterial pressure is required to maintain adequate brain perfusion. As systemic blood pressure falls, a subsequent reduction in brain parenchymal oxygenation occurs. This signals the failure of adaptive mechanisms.

Respiratory failure associated with SE is multifactorial in origin. There is an increase in CO_2 production from the hypermetabolic state, a decrease in respiratory drive, and an increased mechanical load on the respiratory muscles. The decrease in drive (hypoventilation) may be due to muscle fatigue or secondary to medications used to suppress the seizure. There may also be an increase in dead-space ventilation from aspiration or neurogenic pulmonary edema.[41,42]

The cardiovascular changes and initial hyperadrenergic state are due to the release of endogenous catecholamines. Patients will have an initial increase in heart rate and systemic vascular resistance that will decrease over time. Of note, there is an entity called *ictal bradycardia,* which is a rare and probably underestimated manifestation of epileptic seizures whose pathophysiology is still debated. Autonomic modifications may result from either a sympathetic inhibition or a parasympathetic activation probably due to the ictal discharge arising from or spreading to the structures of the central autonomic network.[43]

As the time of the event progresses, it is imperative to prevent hyperpyrexia in these patients as this will contribute to neuronal cell death. Studies in adult patients have shown that there may be a CSF pleocytosis; however, any elevation in the CSF

cell count in a pediatric patient should suggest a possible infectious etiology of the seizure. Prolonged muscle activity may produce an elevation in creatine kinase and produce myoglobinuria and acute kidney injury (AKI) so attention to hydration, electrolyte status, and renal function is essential. Acidemia may be worsened by impaired ventilation, hypoxemia, and anaerobic metabolism. At the cellular level, amino acid excitotoxicity leads to cell injury and death through cascades culminating in intracellular calcium influx.[35-37,44-46]

Evaluation and Management

The clinical presentation of SE is variable, depending on seizure type and the baseline developmental and medical status of the child. Diagnosis depends on the identification of continuous or repetitive seizures, which is usually straightforward in the presence of convulsive seizures. However, after prolonged convulsive seizures the motor manifestations often diminish, and the seizures may become subtle or even nonconvulsive. Differentiating between such nonconvulsive seizures and a postictal state can be challenging. Patients with nonconvulsive SE, including absence SE, may be difficult to identify by history and physical examination alone. These patients can have intermittent altered awareness and continuous lethargy or unresponsiveness with or without subtle myoclonic jerks of the face or limbs. In such cases, continuous EEG (cEEG) monitoring is critical for diagnosis. EEG monitoring also can be used to identify nonepileptic (psychogenic) SE. Although uncommon, prolonged delays in the cEEG-based diagnosis of nonepileptic SE can lead to unnecessary medical intervention.[47]

Common clinical indications for continuous EEG (cEEG) monitoring in the PICU include (1) titration of epileptic drug therapy; (2) screening for subclinical seizures among patients at high risk for conditions such as suspected encephalitis, hypoxic ischemic encephalopathy (postarrest, near drowning), TBI, and stroke; (3) screening for seizures among patients who are paralyzed and at risk for seizures (extracorporeal membrane oxygenation [ECMO]); and (4) characterization of paroxysmal events suspected to represent electrographic seizures. Only half of critically ill children undergoing cEEG monitoring experience their first electrographic seizure during the initial hour of monitoring. Therefore a routine 20- to 30-minute EEG recording will fail to identify the majority of children who go on to develop seizures, justifying the need for cEEG monitoring to accurately diagnose seizures and quantify seizure burden. The majority of electrographic seizures in the PICU are either subclinical or are accompanied by only subtle clinical signs and would likely go undetected without cEEG monitoring.

EEG measures extracellular electrical activity generated by cortical neurons. Data are collected with a standard array of scalp electrodes and presented for visual display onto a paper or digital record.

Because EEG provides real-time information regarding brain activity, it is invaluable in the evaluation of patients with SE, permitting direct correlation between patient behavior and neuronal activity. EEG interpretation should be performed with the assistance of a trained neurologist or neurophysiologist to reduce the potential for both over- and under-identification of seizures.

Abnormal waveforms on EEG can be divided into two categories: epileptiform abnormalities and nonepileptiform abnormalities. Epileptiform abnormalities are abnormal discharges associated with an increased risk of seizures, including sharp

waves, spikes, polyspikes, and spike and slow wave discharges. When present between seizures, these waveforms are termed *interictal abnormalities.* Seizures are defined electrographically by the presence of *ictal* EEG abnormalities, whose hallmark is their rhythmicity and their evolution in frequency or distribution over the course of a seizure. Generalized seizures are characterized by widespread bilateral rhythmic epileptiform discharges (Fig. 67.4A). Focal seizures are characterized by rhythmic epileptiform discharges that are confined to one brain region (Fig. 67.4B). Focal seizures may spread to involve both cerebral hemispheres, a process termed *secondary generalization.*

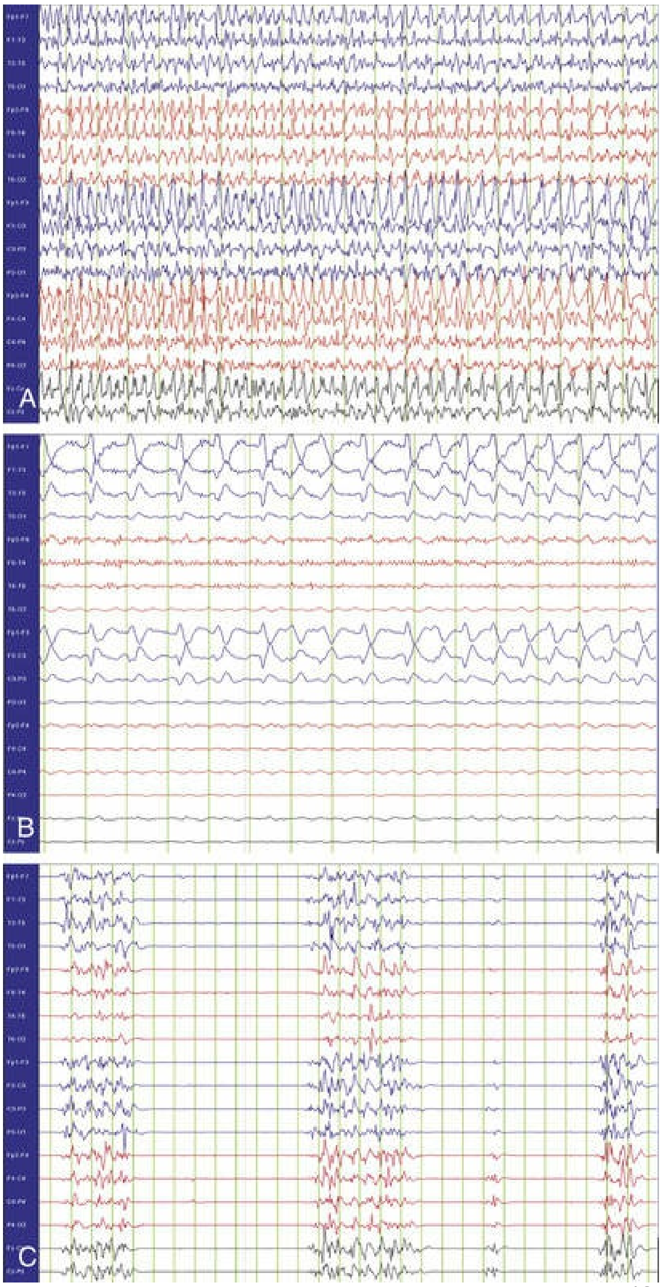

FIG. 67.4 Electroencephalography in status epilepticus (SE). (A) Generalized seizure. (B) Left focal seizure. (C) Burst-suppression pattern in a patient treated with a midazolam infusion for refractory SE.

Nonepileptiform abnormalities are not necessarily associated with a risk of seizure but suggest CNS dysfunction. Slow waves are a nonspecific finding, suggesting a structural or functional abnormality, and often are seen after a seizure or SE. The location of slow waves after a seizure may aid in the differentiation between generalized and focal seizures. Generalized slow waves are associated with a diffuse encephalopathy such as a metabolic disturbance, hypoxia-ischemia, or a postictal state.

Two further EEG patterns are of particular relevance to the treatment of prolonged seizures. Burst suppression is characterized by brief bursts containing a mixture of spikes, sharp waves, and slow waves alternating with periods of very low voltage (Fig. 67.4C). An isoelectric EEG pattern refers to a continuous low-voltage record without any discernable cortical activity. Both burst-suppression and isoelectric EEG patterns can be seen in persons in a coma and may carry a poor prognosis in certain clinical situations. However, in the context of refractory SE, these patterns are often the desired end point for treatment with high-dose barbiturates or benzodiazepines.

Therapeutic goals for SE include (1) general supportive care, (2) termination of SE, (3) prevention of seizure recurrence, (4) correction of precipitating causes, and (5) prevention and treatment of potential complications. Immediate attention to the airway, breathing, and circulation is essential (ABCs). SE is a situation where simultaneous evaluation and management should be undertaken. A suggested clinical approach is summarized in Fig. 67.5.[48,49]

Immediate management

- Noninvasive airway protection and gas exchange with head positioning
- Intubation if needed
- Monitoring O_2 saturation, blood pressure, heart rate, temperature
- Finger stick blood glucose
- Peripheral IV access
- Medical and neurologic examination
- Labs: BMP, magnesium, phosphate, CBC, LFT, coagulation tests, ABG, anticonvulsant levels

Emergent initial therapy (given immediately)

- IV: Lorazepam 0.1 mg/kg IV (max 4 mg)—may repeat if seizures persist
- No IV:
  - Diazepam 2–5 years 0.5 mg/kg, 6–11 years 0.3 mg/kg, 12 years 0.2 g/kg (max 20 mg)
  - Midazolam IM If 13–40 kg then 5 mg. If >40 kg then 10 mg
    - Intranasal 0.2 mg/kg
    - Buccal 0.5 mg/kg
- Consider whether out-of-hospital benzodiazepines have been administered when considering how many doses to administer

Urgent management

- Additional diagnostic testing as indicated: LP, CT, MRI, toxicology labs, inborn errors of metabolism
- Consider EEG monitoring (evaluate for psychogenic status epilepticus or persisting EEG-only seizures)
- Neurologic consultation

Urgent control therapy

- Phenytoin 20 mg/kg IV (may give another 10 mg/kg if needed)—may cause arrhythmia, hypotension, purple glove syndrome
- OR Fosphenytoin 20 PE/kg IV (may be given another 10 PE/kg if needed)
- OR consider phenobarbital, valproate sodium, or levetiracetam

If <2 years, consider pyridoxine 100 mg IV

Refractory status epilepticus

If seizures continue after benzodiazepines and a second antiseizure medication, the patient is in refractory status epilepticus regardless of elapsed time

Continue management and make plans for ICU admission/transfer. Expect need for continuous EEG monitoring once clinically evident seizures terminate to evaluate for persisting EEG-only seizures

Administer another urgent control anticonvulsant or proceed to pharmacologic coma

- Levetiracetam 20–60 mg/kg IV
- Valproate sodium 20–40 mg/kg IV—contraindicated if liver disease, thrombocytopenia, or possible metabolic disease
- Phenobarbital 20–40 mg/kg IV—may cause respiratory depression and hypotension

Pharmacologic coma medications

- Midazolam 0.2 mg/kg bolus (max 10 mg) and then initiate infusion at 0.1 mg/kg/hr. Titrate up as needed
- Pentobarbital 5 mg/kg bolus and then initiate infusion at 0.5 mg/kg/hour. Titrate up as needed
- Other options: Isoflurane

Pharmacologic coma management

- Titrate to either seizure suppression or burst suppression based on EEG monitoring
- Continue pharmacologic coma for 24–48 hours
- Modify antiseizure medications so additional seizure coverage is in place for infusion wean
- Continue diagnostic testing and implementation of etiology-directed therapy

Add-on options

- Medications: phenytoin, phenobarbital, levetiracetam, valproate sodium, topiramate, lacosamide, ketamine, pyridoxine
- Other: epilepsy surgery, ketogenic diet, vagus nerve stimulator, immunomodulation, hypothermia, electroconvulsive therapy

FIG. 67.5 Guidelines for evaluation and management of SE. (From Abend NS, Loddenkemper T. Pediatric status epilepticus management. Curr Opin Pediatr. 2014;26:668-674.)

Although most seizures (~75%)[1] are self-limited and stop in less than 5 minutes, it is reasonable to assume that most children who arrive at the emergency department or PICU have been seizing for a significant length of time. This may include time seizing prior to discovery, time waiting for emergency personnel, time spent en route to the hospital, and time before administration of the first antiepileptic agent. Many patients may have already received potentially sedating medications from family members/EMS personnel that may contribute to respiratory embarrassment

on arrival.

The immediate assessment of the airway begins with a check for patency and reflexes. The airway may be secured by simple maneuvers such as suctioning, positioning, and the use of airway adjuncts (nasal trumpets). High-flow oxygen should be administered and pulse oximetry instituted to evaluate oxygenation status. The presence of nasal flaring, poor chest rise, retractions, cyanosis, abdominal paradoxical breathing, diminished breath sounds, or apnea suggests the patient's trachea should be intubated. It is essential to realize that some patients may require the administration of a neuromuscular blocker (NMB) and if so, it should be one with a short half-life. The NMB agent will stop the motor component of the seizure but will not stop the underlying electrographic seizure activity in the brain. Patients who are going to receive continued paralysis should be simultaneously monitored with cEEG. Patients may be hypovolemic, and the continued addition of medications and positive pressure ventilation may actually worsen hypovolemia and perfusion.

Tachycardia, cool extremities, delayed capillary refill, diminished pulses, and poor urine output suggest poor perfusion. One should follow established Pediatric Advanced Life Support (PALS) guidelines to obtain access and once established the patient may receive isotonic fluid blouses (20 mL/kg). Consideration for the administration of antipyretics should be given early in the management of the patient in SE.

Diagnostic testing in children and adolescents with SE varies among centers and likely reflects the limited evidence supporting most diagnostic approaches in SE. Specific studies should be tailored to match the patient history; however, serum glucose should be checked immediately in all pediatric patients, particularly young infants. Other blood work may include serum electrolytes (sodium, calcium, and magnesium), liver function tests, arterial blood gas, urine toxicology, and antiepileptic levels. Approximately 3.8% to 14.8% of seizure patients who arrived to an ED have electrolyte abnormalities.[50,51] In the event of respiratory, cardiovascular, or neurologic concerns or other contraindications such as a coagulopathy or elevated intracranial pressure and if a lumbar puncture is not done immediately, antibiotics and antivirals (if indicated) should be administered. Although blood cultures and a lumbar puncture have a high yield in children with SE and a clinical suspicion of infection, there is insufficient evidence to either support or refute whether these studies should be routinely performed in children in whom there is no clinical suspicion of infection.[52] Currently evidence to support the performance of most diagnostic tests relies on limited data collected in heterogeneous settings with different study objectives.[53]

One needs to consider nonconvulsive status epilepticus (NCSE) in patients who do not quickly return to their baseline. A study by Allen and colleagues demonstrated that most children regain consciousness within 30 to 40 minutes, although some took many hours to recover without a sinister cause.[54] The two variables determining recovery were seizure etiology and the administration of medications to terminate the seizure. Children recover most quickly from febrile seizures and most slowly from acute symptomatic seizures. The authors stated that “it was surprising that seizure duration did not significantly affect recovery time; clinical dogma is that it does.”[54]

Electrographic seizure activity has been reported to occur in up to 15% of patients whose overt clinical seizures are pharmacologically controlled.[55] NCSE presents with

altered mentation and absent or subtle motor findings (eg, finger twitch) and is therefore defined by EEG criteria. The ictal episodes must be continuous or recurrent for at least 30 minutes without improvement in the patient's clinical state. The incidence of NCSE in pediatrics is currently unknown; however, adult studies have shown a mortality rate between 30% and 50%.[56] Adult studies have also shown that approximately 8% of patients in coma are in NCSE. Adult etiologies included hypoxia and cerebrovascular accident (CVA) as the most common causes followed by infection, metabolic conditions, traumatic brain injury, tumor, and a low AED level.

Pharmacotherapy

A prospective observational study of 182 children with convulsive SE found that for every minute delay between the SE onset and emergency department arrival there was a 5% cumulative increase in the risk of having SE last more than 60 minutes.[57,58] A retrospective study of 154 children with SE compared children with aborted SE and RSE; it demonstrated that in 71 children who continued to seize despite first- and second-line AEDs, seizures were terminated in 100% of cases in which the third AED was administered within 60 minutes of the first and in only 22% of cases if it was administered more than 1 hour after the original AED.[57,59] The new operational SE definition suggests the administration of medication for seizures lasting longer than 5 minutes. Adult data suggest that only a small portion of seizures will progress to SE; however, the longer the seizure lasts, the more difficult it will be to control. The goal of administering an antiepileptic drug is to terminate the event rapidly and safely and to prevent recurrence. First-line medications commonly administered include the benzodiazepines (valium, lorazepam, and midazolam), and second-line agents include phenytoin, fosphenytoin, and phenobarbital. These agents are summarized in Table 67.2. Common errors in the management of SE include insufficient drug dosages, delay in advancing to a second-line drug, and inadequate supportive care. Third-line medications are indicated to treat RSE and are reviewed later in this chapter. An adult clinical review of the management of status epilepticus stated that there are few randomized controlled trials of status epilepticus and that there are poor data and little evidence to support one treatment regimen over another.[60,61]

TABLE 67.2

Drugs Used in the Treatment of Status Epilepticus

Drug	Initial Dose	Maximum Single Dose	IV Administration	Onset of Action	Half-Life	Principal Adverse Effects in Short-Term Use
Lorazepam	0.05–0.1 mg/kg IV	4 mg	0.5 mg/min bolus	1–3 min	Neonates: 40 h Children: 10 h	Sedation, hypotension, bradycardia, respiratory depression, paradoxical hyperactivity
Diazepam	0.05–0.3 mg/kg IV	<5 y: 5 mg ≥5 y: 10 mg	0.1 mg/kg/min bolus	1–3 min	Neonates: 50–95 h Infants: 40–50 h Children: 15–20 h	Sedation, hypotension, bradycardia, respiratory depression, paradoxical hyperactivity, thrombophlebitis
Phenobarbital	15–20	1 g	1 mg/kg/min	5 min	Neonates:	Hypotension, sedation, respiratory depression,

	mg/kg IV		bolus to max. 60 mg/min		45–200 h Infants: 20–133 h Children: 37–73 h	paradoxical hyperactivity, immunosuppression
Pentobarbital	5–12 mg/kg	100 mg	1 mg/kg/h infusion, then titrate	1 min	25 h	Sedation, bradycardia, hypotension, cardiac arrhythmia, respiratory depression, laryngospasm, extravasation causes skin necrosis
Phenytoin	15–20 mg/kg IV	1 g	1 mg/kg/min bolus, to max. 50 mg/min		7–42 h (first-order kinetics do not apply)	Dysarthria, ataxia, sedation, hypotension, cardiac arrhythmia, thrombophlebitis, extravasation causes purple glove syndrome
Fosphenytoin	15–20 mg PE/kg IV	1 g PE	3 mg PE/kg/min bolus to max. 150 mg PE/min		12–29 h (first-order kinetics do not apply)	Dysarthria, ataxia, sedation, hypotension, bradycardia, tachycardia
Valproic acid	10–30 mg/kg IV	30 mg/kg	5 mg/kg/min bolus		Children >2 mo: 7–13 h Children 2–14 y: 3.5–20 h	Hypotension, cardiac arrhythmia, hepatitis, pancreatitis
Paraldehyde	200–400 mg/kg PR	10 g	NA		4–10 h	Rectal irritation, lung toxicity
Midazolam	0.15 mg/kg IV	0.15 mg/kg	1 μg/kg/min infusion, titrate to max. 24 μg/kg/min	1–5 min	Neonates: 4–12 h Children: 3–4 h	Sedation, hypotension, bradycardia, respiratory depression, apnea, laryngospasm, paradoxical hyperactivity
Propofol	1–2 mg/kg IV		1–2 mg/kg/h infusion		1.5–12 h	Sedation, hypotension, bradycardia, respiratory depression, bronchospasm, hallucinations, pain when injected, propofol infusion syndrome, metabolic acidosis, rhabdomyolysis, lipemia, cardiac bradyarrhythmias, death
Ketamine	0.5–2 mg/kg IV		2–7 mg/kg/h[a]	30 sec	2.5 h	Hypertension, increased intracranial pressure, hallucinations, vomiting, emergence reactions, laryngospasm
Thiopental	2–4 mg/kg IV		2–4 mg/kg/h infusion	30–60 sec	14–34 h	Sedation, hypotension, respiratory depression, accumulation due to lipid solubility, extravasation causes skin necrosis
Isoflurane	0.5%–1% v/v		NA			Respiratory depression, hypotension, arrhythmias, malignant hyperthermia, laryngospasm, coughing (due to pungent odor)
Lidocaine	2–3 mg/kg IV		2–6 mg/kg/h		1.5–2 h in adults	Sedation, cardiac arrhythmias

[a]Continuous infusion rates for ketamine are not well established in children; refer to institutional guidelines and experience.

IV, intravenous; *NA*, not applicable; *PE*, phenytoin equivalents; *PR*, rectal; *v/v*, volume per volume.

In current practice there is substantial variability in the initial management of SE. A survey of physicians in Australia and New Zealand reported that first-line management of SE without intravenous (IV) access included rectal diazepam (49%), intramuscular midazolam (41%), and buccal midazolam (9%), whereas first-line management of SE with IV access included midazolam IV (50%) and diazepam (44%).[57] Benzodiazepines remain the first-line drugs in the treatment of SE.[62] Historically, diazepam had been used as the first-line drug; however, lorazepam now is used more often in both the prehospital and hospital setting due to its

minimal side effects. Diazepam and lorazepam were compared in a study funded by the National Institutes of Health (NIH) and coordinated by the Pediatric Emergency Care Applied Research Network (PECARN) to determine which drug is safer and more effective. The results of the randomized clinical trial do not support the hypothesis that lorazepam is superior to diazepam for pediatric SE of at least 5 minutes in duration. Both medications were effective in stopping SE in more than 70% of cases and had rates of severe respiratory depression of less than 20%. Another randomized trial of adults and children, the Rapid Anticonvulsant Medication Prior to Arrival Trial (RAMPART), found, overall, that intramuscular midazolam initiated in the prehospital setting stopped more seizures at arrival to the ED than IV lorazepam; however, a subgroup analysis showed similar results for the two medications. There was also a similar intubation rate of 14% in each group.[63,64]

All three benzodiazepines have an onset of action of less than 5 minutes and enhance inhibitory neurotransmission by binding to a specific benzodiazepine site on the $GABA_A$ receptor. However, diazepam's duration of antiepileptic action appears to be less than 1 hour, making it less attractive than lorazepam. Often patients may have received rectal diazepam prior to arrival to the hospital, and this should be kept in mind as one escalates therapy for SE.[65]

Lorazepam has a slower onset of action than diazepam because it is less lipophilic, but its advantage is its prolonged antiepileptic effect of greater than 6 hours. Currently the Food and Drug Administration (FDA) has approved diazepam for adults and children, whereas lorazepam is approved for adults but is being used off label for children.[66]

Midazolam is a short-acting benzodiazepine used as a first-line agent in prehospital care. It may also be used in the treatment of refractory SE and administered as a continuous infusion. It may be given intravenously, intraosseously, intramuscularly, and per rectum. Small pediatric series have also shown efficacy when given via the buccal or intranasal route as well. The duration of effect is shorter than for lorazepam.[65]

All of the benzodiazepines have the potential to cause respiratory depression and hypotension. Benzodiazepines are less likely to halt seizure activity if multiple dosages are required, and in these situations, additional anticonvulsant medications should be administered. Furthermore, repeated doses of benzodiazepines will have additive sedating effects and may prolong a diminished level of consciousness and prevent adequate neurologic assessment.[65]

Fosphenytoin and phenytoin are preferred second-line, longer-acting AEDs for the treatment of SE. Both drugs exert their effect by stabilizing the neuronal membrane. Each drug takes approximately 20 minutes to achieve a therapeutic effect. Fosphenytoin, a water-soluble disodium phosphate ester of phenytoin, is converted in plasma to phenytoin. Fosphenytoin is compatible with most intravenous solutions, is devoid of propylene glycol, and therefore can be administered at a faster rate and without the cardiovascular risks of phenytoin. Furthermore, fosphenytoin does not have the deleterious effects on tissue as seen with phenytoin in the event of extravasation, nor does it cause respiratory depression or sedation. In most centers, one must order fosphenytoin in phenytoin equivalent (PE) dosages. Although it remains to be proved that the greater speed of administration of fosphenytoin results in improved seizure control compared with phenytoin, fosphenytoin often is preferred because it is better tolerated at the infusion site, carries a lower risk for

cardiac arrhythmia and hypotension, and has not been associated with the purple glove syndrome.[67] The higher cost of fosphenytoin and the lack of definitive evidence for superior efficacy, however, may limit its widespread use, despite the suggestion by pharmacoeconomic analysis that fosphenytoin is cost effective.[68] Although phenytoin is the second-line agent indicated for the treatment of most causes of seizures, it is usually *not* efficacious in the management of drug-induced seizures.

Phenobarbital has a long proven history as an effective antiepileptic drug. It is used commonly to treat neonatal seizures and SE. It may be given intravenously, intraosseously, or intramuscularly. Potential side effects include respiratory depression, hypotension, bradycardia, and prolonged sedation. In particular, prolonged sedation can impair neurologic assessment and is a significant disadvantage of phenobarbital when compared to fosphenytoin and phenytoin. Additionally, the combination of a benzodiazepine and phenobarbital often necessitates tracheal intubation because of respiratory depression.

Propofol is a nonbarbiturate anesthetic agent (GABA agonist) initially approved for rapid induction and maintenance of anesthesia. Its efficacy has been detailed in case reports and small case series and it has been associated with the cessation of seizure activity or burst suppression within seconds of administration.[69] Adverse effects include bradycardia, apnea, and hypotension with rapid infusion. Currently its use has been curtailed in pediatric patients because of the association with the *propofol infusion syndrome,* which includes potentially fatal metabolic acidosis, rhabdomyolysis, and cardiovascular collapse. This agent is not approved for use in status epilepticus in pediatric patients.[70,71]

Valproic acid (VPA) is a common antiepileptic drug with case series describing the use of intravenous VPA for treatment of SE and RSE.[72-76] Possible mechanisms of action include an increase in CNS GABA levels by increased synthesis and decreased catabolism, blockade of T-type Ca^{++} currents, and enhancement of Na^{+} channel inactivation. VPA was found to be an effective treatment leading to termination in seizure activity in 78% of 41 children included in the series. Patients were initially loaded with 20- to 40-mg/kg VPA, diluted 1 : 1 with normal saline or 5% dextrose, and infused over 1 to 5 minutes. An IV infusion of 5 mg/kg/hr followed the loading dose. The infusion was decreased by 1 mg/kg every 2 hours once a 12-hour seizure-free period was attained. Overall, seizures were terminated in 78% with 65.9% responding after the initial bolus. The FDA has not yet approved IV valproic acid for treating SE.[77,78]

Levetiracetam has no effect on voltage-gated Na channels or GABAergic transmission and no affinity for either GABAergic or glutamatergic receptors. Some have proposed that it binds to a presynaptic vesicle glycoprotein (sv2A) to act as a transporter for presynaptic P/Q type voltage-dependent calcium channels. It has been considered a potentially useful agent for SE because, in comparison with other IV AEDs, it has few known side effects, including a low risk of sedation, cardiorespiratory depression, or coagulopathy, and thus it is potentially useful in critically ill children. Clearance is dependent on renal function and completely avoids hepatic metabolism.[79-81]

Lacosamide is a functionalized amino acid that selectively enhances slow inactivation of voltage-gated sodium channels, increasing the proportion of sodium channels unavailable for depolarization. This stabilizes neuronal membranes and

inhibits sustained repetitive neuronal firing. In randomized controlled trials in adults, it demonstrated significant benefit in treating refractory seizures, with 30% to 40% of patients achieving a >50% reduction in seizures at doses of 400 to 600 mg/day. Pediatric studies describe similar results in children and young adults with refractory epilepsy.[82] It is generally well tolerated, and the most frequent reactions are dizziness, headache, diplopia, and nausea. These adverse effects are usually dose related and reversible on dose reduction or discontinuance.

There are no controlled, randomized, blinded clinical trials to compare the efficacy and tolerability of currently available treatments for established status epilepticus (ESE), defined as seizures that continue despite the administration of a benzodiazepine. An ongoing study titled the Established Status Epilepticus Treatment Trial (ESETT)[83] is attempting to determine the most effective or the least effective treatment of benzodiazepine-refractory SE among patients older than 2 years. Three active treatment arms are being compared: fosphenytoin, levetiracetam, and valproic acid. Other objectives include comparing the three drugs for secondary outcomes and to describe effectiveness, safety, and rate of adverse reactions to these drugs in children.

Refractory Status Epilepticus

SE that persists beyond 1 hour despite AED therapy is considered refractory (RSE). About 30% of SE cases may prove resistant to standard treatment with one of the benzodiazepines and phenytoin. This subgroup of patients has a higher risk of complications and longer hospital stay and mortality. Most of them have some structural cerebral damage or metabolic disorders or cerebral hypoxia. Other risk factors include delay in receiving treatment, metabolic encephalopathy, hypoxia, and encephalitis.[84]

Conventional AEDs have low efficacy in RSE, and although conventional AEDs (eg, topiramate, levetiracetam, and carbamazepine) should be continued during this treatment phase, higher dose or higher potency agents are required to abort RSE. Therapeutic options include high-dose benzodiazepines, barbiturates, propofol, valproic acid, ketamine, lidocaine, and inhalational anesthetic agents. Currently, insufficient evidence exists to conclude which of these high-dose suppressive medications, either alone or in combination, has superior efficacy in the treatment of RSE.[85]

Goals of Therapy

In the treatment of RSE, as in SE, the goal is termination of all clinical and electrographic seizure activity, and thus cEEG monitoring is required. ICU practitioners should resist the temptation to assess seizure control on the basis of clinical signs alone because the clinical expression of seizures can be subtle and the examination is often confounded by the use of sedative medications. Therefore treatment of RSE should be guided by cEEG monitoring. However, the exact target of cEEG-guided therapy remains controversial. In addition to achieving seizure suppression, it is generally recommended to escalate therapy to achieve a burst-suppression pattern on EEG. The rationale for achieving burst suppression is that profound suppression of brain activity may have a protective effect and break the

cycle of seizures, thus reducing the chance of seizure recurrence upon tapering of medications.[86] Debate continues regarding the recommended length of the periods of EEG suppression (the interburst interval) and how long the burst-suppression pattern should be maintained. Furthermore, because of a concern that seizures may persist even when the EEG is interspersed with a burst-suppression pattern, some experts recommend achieving complete EEG suppression—in other words, an isoelectric EEG pattern.[87] As a general approach, once seizure control or a burst-suppression pattern has been achieved, a suggested practice is to maintain the burst-suppression pattern for at least 12 hours before a medication taper is attempted. If seizures recur when medication is tapered, then therapy is reinstated to achieve a burst-suppression pattern for at least another 48 hours.[88,89]

In parallel with high-dose suppressive therapies described in detail in the following sections, conventional AEDs (ie, topiramate, levetiracetam, and carbamazepine) should be titrated to high therapeutic doses, both to assist in aborting RSE and to provide continued anticonvulsant coverage following tapering of high-dose suppressive therapies.

High-Dose Barbiturates

Barbiturates including pentobarbital, thiopental, and phenobarbital are widely used medications for RSE that also may have neuroprotective effects.[90] Pentobarbital is the best-studied drug, and the most data are available on its use. Pentobarbital is administered as an intravenous loading dose of 5 to 10 mg/kg, followed by a continuous infusion of 1 mg/kg/h, increasing as needed to a maximum rate of 10 mg/kg/h. Breakthrough seizures may be treated with additional boluses of 3 to 5 mg/kg.[91] High-dose phenobarbital is an alternative to pentobarbital. Phenobarbital may be given in incremental boluses of 10 mg/kg, without reference to a predetermined maximum level or dose, until seizures are suppressed. There appears to be no maximum dose beyond which further doses are ineffective, and serum levels of up to 344 mg/mL (1490 mmol/L) have been reported.[92] The main drawback of barbiturates in high doses is the risk of cardiovascular depression and hypotension. This situation frequently requires inotropic and vasopressor therapy and, in rare instances, cardiopulmonary resuscitation. In addition, the need for mechanical ventilation and the time to regain consciousness are also greater with barbiturates than with benzodiazepines.[85] Among the barbiturates, phenobarbital probably carries the lowest risk of hypotension and respiratory depression.[92] Finally, evidence indicates that high-dose, prolonged barbiturate therapy is immunosuppressive, thus particular vigilance for nosocomial infections is indicated.[93,94]

High-Dose Benzodiazepines

Midazolam is a short-acting benzodiazepine with an efficacy equal to pentobarbital in controlling RSE.[95] It is administered as a loading dose of 0.15 mg/kg, followed by a continuous infusion beginning at 1 μg/kg/min. The infusion rate may be increased as tolerated to a maximum of 24 μg/kg/min, although even higher infusion rates have been reported. The advantages of midazolam include a rapid onset of action, a short half-life, and a lower incidence of cardiovascular depression and need for

vasopressors than with pentobarbital.[85,96] The major disadvantage of midazolam is the need for escalating doses because of tachyphylaxis. High-dose infusions of diazepam and lorazepam represent other alternatives.[97,98]

Propofol

The GABA agonist propofol is an anesthetic agent with potent anticonvulsant properties that has been widely used for the treatment of RSE, particularly in adults. The advantage of propofol is its rapid onset of action and short half-life; however, rapidly tapering propofol can precipitate seizures.[99] The main adverse effects of propofol are respiratory depression and hypotension due to myocardial depression. Early concerns about a possible proconvulsant effect of propofol have been largely allayed.[100,101] The use of propofol, particularly at high doses and with prolonged infusions, has been associated with a so-called propofol infusion syndrome characterized by metabolic acidosis, lipemia, rhabdomyolysis, bradyarrhythmias, and death.[102,103] A retrospective series of 31 adults treated with propofol for RSE found a 6% mortality rate and a 10% rate of cardiorespiratory arrest directly attributable to the propofol infusion syndrome. In addition, 39% of patients developed one or more features of the syndrome.[104] Therefore propofol infusions should be used with caution and should be limited to short duration with careful monitoring for adverse effects. Few data have been published on pediatric dosing of propofol for RSE. One case series reported safety and efficacy using a bolus dose of 1 to 2 mg/kg, followed by a continuous infusion of 1 to 2 mg/kg/h.[105,106]

Valproic Acid

Intravenous valproic acid may have a useful role in RSE, but relatively little evidence exists to support its use.[107] In one case series, the authors reported on the efficacy of intravenous valproic acid for generalized convulsive and nonconvulsive seizures in children. They recommended a loading dose of 20 mg/kg followed by an infusion at 1 to 4 mg/kg/h, depending on the patient's state of hepatic induction (1 mg/kg/h for noninduced, 2 mg/kg/h in the presence of polyanticonvulsant therapy, and 4 mg/kg/h for high-dose pentobarbital).[108] In a subsequent retrospective review of 40 children (18 with SE), the researchers reported on the safety and efficacy of valproic acid when administered at loading doses of 25 mg/kg (in valproate-naive patients) and infused at rates of 2 to 3 mg/kg/min.[109] No significant changes were noted in heart rate or rhythm, blood pressure, or liver enzymes. One patient reported a transient tremor after the infusion.

Inhalational Anesthetics

Several reports describe the efficacy of inhalational anesthetics for SE that is refractory to high-dose benzodiazepines and barbiturates.[110,111] Inhalational anesthetics have the advantage of being easily titratable; however, prolonged use (particularly of halothane) may cause organotoxicity. Hemodynamic compromise is seen with all of these agents, particularly halothane, and all patients in reported studies required vasopressors. In adults, achieving isoelectric EEGs has required isoflurane concentrations of 1.5% to 2%.[112] The use of inhalational anesthetics in the

ICU setting is complicated by the need for a proper gas scavenging system and supervision by staff trained in the administration of anesthesia.

Ketamine and Lidocaine

Ketamine is a unique NMDA antagonist reported to have both anticonvulsant and neuroprotective properties. Because of its unique mechanism of action on NMDA receptors, ketamine is an attractive therapeutic option for refractory SE that has failed to respond to high-dose benzodiazepines and barbiturates.[113] Ketamine is commonly used for procedural sedation, but there is no consensus on its dosing for SE, particularly when given as a continuous infusion. Lidocaine, which is given as an intravenous bolus or a continuous infusion, is another treatment option, although it is not widely used in North America.[114]

Pyridoxine

Pyridoxine (vitamin B_6) is a cofactor for both glutamic acid decarboxylase and GABA transaminase, the enzymes required for the synthesis and metabolism of GABA in the brain. Pyridoxine dependency and pyridoxine deficiency are rare disorders (with a prevalence of ~1/300,000 in the United Kingdom) that usually present in the neonatal or infantile period but may present as late as age 2.5 years.[115] Patients with these disorders have intractable seizures that are refractory to conventional anticonvulsant medications but respond promptly to pyridoxine. Therefore a trial of pyridoxine should be considered in any child who is seen before age 3 years with recurrent seizures or SE, particularly if the seizures are refractory to conventional anticonvulsant agents.[115] Isoniazid poisoning is another clinical scenario in which pyridoxine may be the only effective anticonvulsant therapy.

Midazolam as a constant infusion has been reported in children with RSE[116] with surprisingly few adverse effects. Initially the patient is given a 0.15-mg/kg bolus followed by a constant infusion of 1 μg/kg/min. The infusion is increased by 1 μg/kg/min every 15 minutes until seizures are controlled. Continuous EEG monitoring and personnel well skilled in interpretation are essential to the success of therapy. In a case series of children with RSE, seizures were controlled in a mean time of 0.78 hours with infusions ranging from 1 to 18 μg/kg/min. Once seizures are controlled, the infusion rate is decreased after 12 to 24 hours while closely monitoring for seizure recurrence. All prior anticonvulsants should be continued during this phase of treatment. An interesting question is, why would midazolam work after lorazepam and valium have failed?[117,118]

Pentobarbital is often used as the next step in patients with RSE. It is advised that patients be placed on mechanical ventilation and will probably require placement of a central venous catheter and invasive blood pressure monitoring. The goal of pentobarbital therapy is to achieve an EEG pattern of burst suppression. Pentobarbital is a myocardial depressant, and hypotension requiring volume expanders and vasopressors is common. After 12 to 24 hours of burst suppression the infusion is reduced and the patient is monitored for clinical or electrographic seizure activity. If seizures recur, pentobarbital is increased to the rate that achieved burst suppression, more time is allowed to transpire (usually 12–24 hours), and another attempt at dose reduction is made.

Hypothermia

Therapeutic hypothermia has been used to treat RSE and super-refractory SE (SRSE) for many years.[89,118,119] Considering its immediate effect on epileptiform discharges in animal models, its mechanism of action seems to be different from those speculated in other neurologic conditions. Gilliam described its use in 5 children with RSE and reviewed 7 other children reported in the literature. Nine of these 12 had failed to respond midazolam, 4 also failed to respond to pentobarbital, and 1 had not responded to ketamine.[118] In all cases, body cooling to 32° to 35.3°C achieved acute seizure control. Although hypothermia may help control RSE and SRSE, its effect is transient and should be considered a temporizing measure while other AEDs are considered.[119,120]

Ketogenic Diet

The ketogenic diet is a high-fat, low-carbohydrate, and adequate protein diet used to treat pediatric seizures. It has also been used to treat RSE and SRSE. Pediatric series to date demonstrated that 33 of 43 children had responded within 19 days.[121-125]

Surgical Options

Despite exciting developments in the medical management of pediatric epilepsy, a subpopulation of approximately 30% will remain refractory to multiple AEDs. Medically refractory epilepsy threatens the developing brain, thus early identification and treatment will allow for better outcomes in this group of patients. Developments in monitoring (subdural grids) and neuroimaging (CT, MRI, positron emission tomography [PET], and single photon emission computed tomography [SPECT] scans) along with safer surgical techniques have allowed neurosurgeons to consider possible surgical evaluation and management of these patients.

Patients to be considered for epilepsy surgery must have medically refractory and disabling seizures. These patients are then evaluated by an experienced epilepsy team and undergo noninvasive (scalp EEG) and invasive monitoring (subdural grids and strips if needed), structural imaging (MRI), and functional imaging (SPECT, PET).[126,127]

When SE is refractory to multiple medical treatments, including high-dose barbiturates and benzodiazepines, surgical intervention can be considered by centers with experience in pediatric epilepsy surgery. This approach is most easily considered for but not limited to children with a large cortical malformation.[128] Focal cortical resections may be indicated if a focal structural abnormality can be identified on neuroimaging; however, the presence of a lesion on MRI is not sufficient to ensure that seizures are arising from that region. Seizures also may arise from regions remote from a lesion visualized by MRI. Furthermore, in children with prolonged RSE, secondary epileptogenic foci may develop. Typically, multiple investigations will be undertaken to ensure that seizures are arising from the area of potential surgical resection. At a minimum, there should be concordance between the structural lesion and the location of ictal and interictal EEG discharges. If the patient is medically stable, fluorodeoxyglucose positron emission tomography may be used to demonstrate interictal hypometabolism or ictal hypermetabolism of the epileptogenic focus, and magnetoencephalography may be used to support the

identification of the epileptogenic focus.[129] Magnetoencephalography is a relatively new functional imaging modality that delineates the epileptogenic zone by detecting magnetic fields produced by interictal epileptiform activity. Implantation of subdural electrodes allows for the most precise localization of the epileptogenic focus; however, this procedure usually is not feasible in the setting of RSE. The evidence for such surgical approaches is limited to case reports and smaller series.[128,130-132]

Specific groups that may possibly benefit from surgical intervention include those with cortical dysplasia, tuberous sclerosis complex, polymicrogyria, hypothalamic hamartoma, hemispheric syndromes, Sturge-Weber syndrome, Rasmussen syndrome, and Landau-Kleffner syndrome. These patients should be referred to a center with expertise in pediatric epilepsy surgery. Surgical procedures may include placement of a vagal nerve stimulator (VNS), resection of a cortical lesion, temporal lobectomy, hemispherectomy, corpus callosotomy (disconnection), or multiple subpial transaction.[133]

VNSs are placed in patients with refractory partial seizures that are not surgical candidates because they lack a resectable seizure focus. The mechanism of action is not known, but it is thought that electrical stimulation may increase the degree of inhibition or decrease the degree of excitation in the CNS. The VNS reduces seizure frequency but does not ablate or destroy a seizure focus, nor does it anatomically disrupt a functional connection from the epileptogenic cortex to surrounding cortex. Outcome data are generally good with a reduction in seizure frequency of more than 50% in 50% to 75% of patients. Postoperative complications include coughing, hoarseness, and throat paresthesias during stimulation.[134-136]

Morbidity and Mortality

The mortality associated with pediatric SE has declined from approximately 11% in 1970 to 3.6% in 1989.[137] The need for admission to a PICU increases the mortality to approximately 6%.[138] Outcome is related to the duration of the seizure, the age of the patient, and the underlying CNS disorder. Patients who remain in SE >1 hour and are less than 1-year-old have the highest risk of mortality. The mortality rate of RSE is approximately 32%, which is much higher than the overall mortality cited earlier for patients with SE. Patients who suffer prolonged seizures also have higher morbidity such as developmental delay and new-onset epilepsy.[139] Overall, children with epilepsy have an increased risk of death; however, most deaths occur in those with severe underlying conditions and are not directly related to the occurrence of seizures.[140-142]

CHAPTER 68

Hypoxic-Ischemic Encephalopathy

Pathobiology and Therapy of the Postresuscitation Syndrome in Children

Ericka L. Fink, Robert S.B. Clark, Hülya Bayir, Cameron Dezfulian, Patrick M. Kochanek

PEARLS

- Cardiac arrest in pediatric patients differs from cardiac arrest in adult patients in at least two important aspects: (1) cardiac arrest in pediatric patients is predominantly due to asphyxia, in contrast to adults, where it is more often due to ventricular dysrhythmias, and (2) developmental differences between pediatric and adult patients including ongoing synaptogenesis, lower cerebral blood flow in neonates and higher cerebral blood flow in toddlers and children compared with adults, neurotransmitter receptor maturation, and higher energy expenditure in pediatric patients.
- In 2010, the American Heart Association stated that therapeutic hypothermia (32° to 34°C) may be considered for children who remain comatose after cardiac arrest, although it is reasonable for adolescents resuscitated from sudden, witnessed, out-of-hospital ventricular tachycardia/fibrillation cardiac arrest.[1] A multicenter, randomized clinical trial evaluating 48 hours of hypothermia versus controlled normothermia found no benefit of hypothermia in out-of-hospital pediatric cardiac arrest; results from the in-hospital study are pending.
- At present, there is no clinically proved brain-targeted therapy for hypoxic-ischemic encephalopathy. It is likely that such targeted therapies, spanning field interventions, intensive care, and rehabilitation, will be required to mitigate hypoxic-ischemic encephalopathy in infants and children after cardiac arrest.

Hypoxic-ischemic encephalopathy (HIE) in children surviving cardiac arrest is a significant public health problem and confers a lifelong burden on patients and

families. Despite the lack of new targeted therapies for HIE, outcomes for some children after in-hospital pediatric cardiac arrest are improving, which is likely multifactorial.[2] From 2002 to 2005, important clinical trials demonstrated neuroprotective effects of therapeutic hypothermia in adults with cardiac arrest and neonates with moderate to severe HIE.[3-7] Although these studies and an increased understanding of mechanisms of HIE provide hope, challenges remain as the likelihood of intact neurologic survival in children who suffer cardiac arrest remains unacceptably small.[8,9] These trials spurred interest in determining whether therapeutic hypothermia is efficacious in children after cardiac arrest, culminating in a National Institutes of Health–funded multicenter clinical trial of therapeutic hypothermia after pediatric cardiac arrest (THAPCA) in the United States, Canada, and the United Kingdom. Although accrual for this study occurred, questions developed regarding the optimal temperature target for neuroprotection with publication of a randomized clinical trial (RCT) in adults with cardiac cause of cardiac arrest that found similar outcomes when targeting 33°C or 36°C.[10] The out-of-hospital pediatric cardiac arrest THAPCA trial found no difference in survival with favorable outcome; in-hospital results are pending.[11] Thus a proved effective treatment protocol that reliably prevents HIE and improves neurologic recovery after cardiac arrest in infants and children remains elusive. Even the optimal supportive care and monitoring to minimize secondary organ injury and maximize recovery after cardiac arrest are in and of themselves controversial.

A key question is whether or not more advanced monitoring of the brain with titration of supportive care, at least in part, to brain-related pathophysiologic derangements will improve outcomes. This question arises from the pathobiological complexity of cerebral injury and the limitations to monitor key metabolic and physiologic parameters in the brain. This question is beginning to be addressed in both preclinical and clinical investigations via brain tissue oxygen monitoring and intracerebral microdialysis.[12,13] Clinical stumbling blocks in the history of brain resuscitation have also slowed our understanding of HIE after cardiac arrest. Historically, this entity was largely ignored as a specific disease process. Brain resuscitation was dealt with as a single therapeutic paradigm regardless of the etiology.[14] This resulted in the misguided application of results from studies of traumatic brain injury (TBI), stroke, Reye syndrome, and cerebral protection to patients suffering cardiac arrest. Second, within cardiac arrest, etiologies and patient-relevant biological factors are lumped together. Factors influencing neurologic damage and recovery are clearly different depending on the cause (asphyxia, arrhythmia, hemorrhage, trauma, sepsis, etc.), age, comorbidities, genetic factors, interval between arrest and return of spontaneous circulation (ROSC), and effectiveness of cardiopulmonary resuscitation (CPR).

This chapter reviews the pathobiology of HIE with emphasis on cellular mechanisms, pathophysiology, and histopathology. Differences between the most prevalent etiologies of cardiac arrest in children (asphyxia versus cardiac arrhythmia) are examined, and an appraisal of traditional and novel therapies is presented. Finally, any discussion of HIE in children is complicated not only by the specific mode of arrest in children but also by the unique nature of these young patients. The child's brain is still developing, adding another layer of variability in terms of age-specific pathologic and reparative mechanisms, potential for therapies to afford benefit, evaluation of therapeutic effectiveness, and neurologic outcome.

Thus the effect of the host's immaturity on the pathobiology of postarrest encephalopathy also is examined.

Epidemiology

In the United States, cardiac arrest occurs in 8 to 20/100,000 children per year in the out-of-hospital setting and in 1.06 of every 1000 pediatric hospital admissions[8,15,16] resulting in roughly two to three many times as many in-hospital as out-of-hospital cases.[9] Males have an increased frequency of cardiac arrest (60% versus 40% for females), but there are no sex differences in mortality.[9] Half of children with cardiac arrest have underlying comorbidities.[9,17]

Asphyxia is the most frequent cause of cardiac arrests and the principal cause of HIE in children.[18,19] In asphyxial arrest, asystole or pulseless electrical activity (PEA) is preceded and precipitated by a period of hypoxemic or anoxic perfusion.[20] Studies are beginning to define the cascade of events that ultimately leads to no flow during asphyxia, and these studies have revealed specific cardiovascular phases and remarkable brain-heart interactions.[21] Hypoxia most commonly results from submersion accidents, airway obstruction, pulmonary aspiration, severe asthma or pneumonia, inhalation injury, or apnea syndromes.[8,9,22] In ventricular fibrillation (VF)-induced cardiac arrest, respiration ceases shortly after loss of perfusion pressure. VF also occurs in children but at an estimated incidence of <10% of pediatric victims of cardiac arrest overall.[9]

Although most in-hospital events are witnessed with bystander CPR performed by health care personnel, less than one-third of out-of-hospital events are witnessed with 30% to 50% of those children receiving bystander CPR, and this distinction influences outcome.[22,23] The largest proportion of unwitnessed out-of-hospital cardiac arrest occurs in infants (86%), the age group with the worst outcomes.[23]

Cellular and Molecular Pathobiology

Mechanisms of Hypoxic-Ischemic Brain Injury

Cerebral neurons in culture can tolerate hours of extreme hypoxia. Although it takes about 160 minutes of exposure to an anoxic gas mixture for oxygen tension in the culture medium to reach 1 mm Hg, cortical neurons tolerate 1 to 3 additional hours with little histologic change.[24] If 1 mmol/L sodium cyanide is used to simulate immediate anoxia, hippocampal neurons become swollen and vacuolated within 20 to 60 minutes and begin to disintegrate in 4 hours. Similarly, even 1 hour of complete global brain ischemia in monkeys is followed by electrophysiologic recovery of many neurons and significant recovery of some aspects of brain metabolism, such as protein synthesis.[25] Although the time limit for consistently normal outcome after normothermic cardiac arrest is unknown, it is certainly closer to 5 to 10 minutes than 1 to 3 hours. Restoration of integrated brain function—that is, neurologic recovery—differs markedly from physiologic or metabolic brain recovery. In contrast to the relative cellular homogeneity in other organs, the functional specificity and interactions of neurons and glia in the brain make patchy areas of cell death potentially devastating. This is evident in the neuropathology of dogs in persistent coma 1 week after a 10- to 15-minute cardiac arrest. Scattered, regionally dependent

neuronal death is evident, but the majority of neurons appear normal.[26] Cardiac arrest is unique from other forms of focal brain ischemia and nonischemic brain injury in that survival requires reperfusion. Reperfusion injury is therefore a mandatory part of the postischemic recovery period and may contribute to the unique phenotype of hypoxic-ischemic brain injury.

Energy Failure

The brain depends on large amounts of substrate (glucose and lactate) because of its tremendous metabolic demands and paltry energy stores. Interruption of cerebral blood flow (CBF) results in loss of consciousness and electroencephalographic silence within seconds. Within 5 to 7 minutes, energy failure occurs, accompanied by disturbances of ion homeostasis in neurons and glial cells. Clinically this rapid depletion of brain high-energy phosphates has been demonstrated after hypoxia-ischemia in neonates using phosphorus magnetic resonance spectroscopy (MRS).[27] Influx of sodium and water and efflux of potassium occur because the cells cannot maintain their energy-dependent electrochemical gradients. When the extracellular potassium concentration reaches 10 to 15 mmol/L, voltage-gated channels open and extracellular calcium influx occurs.[28]

If CBF remains inadequate and energy failure persists, calcium-mediated events such as phospholipase and protease activation can lead to irreversible injury and neuronal cell death. Cerebral acidosis occurs, and intracellular pH decreases from 7 to 6.4.[29] If CBF is restored, however, recovery of basal cellular metabolism (adenosine triphosphate [ATP] levels, protein synthesis, oxygen consumption) and pH occurs. This has been shown in brain tissue samples and intact brain measurements after global ischemic insults that result in a persistent minimally conscious state.[25]

After anoxia or ischemia, the recovery of aerobic metabolism is essential for recovery, but is not in-and-of-itself sufficient. The imbalance between aerobic and anaerobic metabolism and over-dependence of neurons upon lactate as a substrate[30] must be restored. Despite global metabolic recovery, certain neurons progress to cell death. After restitution of CBF and oxidative metabolism after energy failure in the brain cellular and molecular dysfunction can progress and cells may die via immediate necrosis (complete energy failure), programmed cell death (apoptosis, autophagic stress, or regulated necrosis), or a spectrum of these processes (see also Chapter 84).[31-33] Brain MRS demonstrates early (during ischemia) and late (48 hours after reperfusion) depletion of high energy phosphorous compounds and a corresponding lactate peak occurring in the face of normal vital signs, serum glucose, and arterial oxygen saturation after experimental hypoxia-ischemia.[34,35]

Selective Vulnerability

Certain neurons—such as those in the CA_1 region of the hippocampus; basal ganglia; cerebral cortical layers III and V; portions of the amygdaloid nucleus; the cerebellar Purkinje cells; and, in infants, periventricular white matter regions and some brain stem nuclei—are known to be especially vulnerable to global hypoxia-ischemia and reperfusion.[36,37] Five minutes of complete global brain ischemia produces cell death in the regions that begin to appear between 48 and 72 hours, without apparent histologic damage in other brain areas.

Transient calcium accumulation occurs in all cells during ischemia, but secondary

irreversible accumulation occurs in the selectively vulnerable zones many hours later.[38] Electrophysiologic studies show that delayed neuronal death is preceded by neuronal hyperactivity. It is hypothesized that ischemic and early postischemic calcium accumulation leads to a complex sequence of derangements in cellular metabolism such as protease activation and oxygen-derived free radical formation.[39] These conditions, in concert with excessive release of excitatory neurotransmitters (glutamate, glycine, aspartate) in these areas, lead to excitotoxicity and cell death. These findings are supported by work in neuronal culture showing that calcium influx accompanies cell death in the presence of anoxia or supraphysiologic levels of excitatory amino acids such as glutamate,[24,40] and that CA_1 cells are the most sensitive to glutamate-mediated injury.[41] Finally, delayed energy depletion, mitochondrial dysfunction, and infarction occur in concert but are regionally distinct, suggesting that metabolic characteristics of brain regions affect recovery from ischemia.[42,43]

Of particular interest is that these intrinsically vulnerable cells do not have a unique vascular distribution.[44] They represent neither vascular watersheds nor hypoperfused zones during reperfusion. Death of these neurons after a threshold ischemic insult occurs in a delayed fashion following reperfusion and thus may be preventable, at least in part, by treatment.

Cell Death Mechanisms

Cell death can occur by multiple distinct pathways, necrosis, apoptosis, or autophagy, but overlap and combination exists, and a number of additional neuronal death pathways including necroptosis, pyroptosis, and ferroptosis have been identified, although their contribution to brain injury after cardiac arrest remains to be defined.[31,45-48] Necrosis, which is characterized by denaturing and coagulation of cellular proteins, is the basic pattern of pathologic cell death that results from a progressive reduction in the cellular content of ATP.[49] Necrosis involves progressive derangements in energy and substrate metabolism that are followed by a series of morphologic alterations including swelling of cells and organelles, subsurface cellular blebbing, amorphous deposits in mitochondria, condensation of nuclear chromatin, and, finally, breaks in plasma and organellar membranes.[49] Although necrotic cell death was traditionally felt to be entirely irreversible, studies showing that some degree of necrotic cell death responds to treatment after hypoxia-ischemia implicate regulated or programmed necrosis also termed *necroptosis*.[50,51]

Cell death after hypoxic-ischemic insults can also occur by apoptosis.[52] Development of apoptosis usually requires new protein synthesis and the activation of endonucleases. Two distinct types of characteristic cleavage of DNA have been described. The most well described, *caspase-dependent* apoptosis, involves cleavage by caspase-activated deoxyribonuclease at linkage regions between nucleosomes to form fragments of double-stranded DNA.[53] This produces a pattern of DNA cleavage observed on Southern blot analysis termed *DNA laddering.* In contrast, *caspase-independent* apoptosis results in large-scale DNA fragmentation induced by the mitochondrial flavoprotein apoptosis-inducing factor (AIF).[54,55] The stimuli triggering apoptosis are complex and multifactorial, involving extracellular surface receptors, cell signaling pathways, protease cascades, and mitochondrial and other

organelle dysfunction. Selective vulnerable cell death in brain regions such as the CA_1 region of the hippocampus after transient global brain ischemia appears to occur by apoptosis,[56] as DNA extracted from the hippocampus of gerbils at 4 days after a threshold global ischemic insult exhibits the characteristic laddering pattern. Thalamic delayed neuronal death was caused by Fas-mediated apoptosis in a model of neonatal hypoxia-ischemia,[57] and durable electrophysiologic disturbances are observed in thalami after asphyxia cardiac arrest in juvenile rats.[58] Li and colleagues[59] reported that apoptosis in the postischemic brain is not limited to scattered neuronal death in what have been traditionally deemed to be selectively vulnerable regions, but it is seen even in penumbral regions around evolving cerebral infarcts (Fig. 68.1). Finally, the proportion of apoptosis in the developing brain after ischemia appears to be sex dependent, as females but not males respond to antiapoptotic agents after neonatal hypoxia-ischemia.[60]

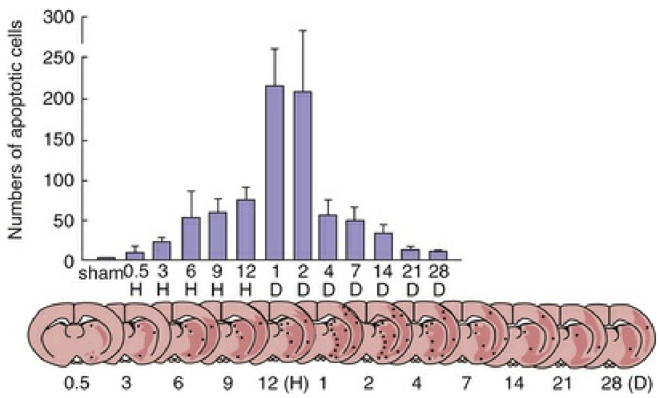

FIG. 68.1 Apoptotic cells in coronal brain sections in rats subjected to 2 hours of middle cerebral artery occlusion and between 0.5 and 28 days of reperfusion. *Top:* Progressive increase in the numbers of apoptotic cells occurs with increasing reperfusion time to peak at 24 hours. However, apoptotic cells are still detectable even after 1 week of reperfusion. *Bottom:* Distribution of apoptosis (*dots*) and necrotic neurons (*hatched areas*). Apoptotic cells are localized predominately to the inner boundary zone of infarction. (From Li Y, Chopp M, Jiang N, Yao F, Zaloga C. Temporal profile of in situ DNA fragmentation after transient middle cerebral artery occlusion in the rat. J Cereb Blood Flow Metab. 1995;15:389-397.)

Autophagy is a homeostatic process that recycles cell resources during periods of nutrient stress.[61] Autophagy is up-regulated after experimental brain ischemia,[62,63] which can be considered profound nutrient stress.[64] Studies show that blocking autophagy after hypoxia-ischemia can be protective or detrimental.[48,65,66] As such, autophagy's role after acute brain injury is controversial, and it may depend on the stage of brain development and sex of the patient, animal, or cell.[64,67] Mouse pups lacking Atg7 (a necessary component for autophagy) or rat pups treated with an inhibitor of autophagy (3-methyladenine) are protected from focal hypoxia-ischemia.[62,63] Knockdown of Atg7 using small interfering RNA (siRNA) was shown to reduce autophagy and Purkinje neuron death in juvenile rats after asphyxia cardiac arrest, with the beneficial effects more prominent in female versus male rat pups.[68]

The proportion of neuronal death that occurs via apoptosis, necrosis, autophagy,

or other pathways after cerebral ischemia remains undetermined.[69,70] Although neurons may appear histologically normal in the days after reperfusion, electron microscopy reveals changes present within 6 hours.[70] Moreover, it remains possible that treatments inhibiting apoptosis, for example, may simply convert cell death to necrosis or autophagy, or another pathway.[71,72] Although speculative, it is possible that after cardiac arrest and resuscitation, a continuum exists in neurons from recovery to necrosis[73] that depends on the duration of the insult, the local milieu, and the given brain region.[74-76]

Nevertheless, in any given brain region, irrespective of the neuronal death pathway that is activated, a highly complex series of events occurs during the arrest and after ROSC. A theoretic scheme of the mechanisms involved is given in Fig. 68.2, a scheme that remains remarkably contemporary despite being conceptualized in the 1990s by Bellamy, Safar, and others.[77] Importantly, several molecular and pharmacologic interventions that interrupt apoptosis have been reported to improve outcome after cerebral ischemia, including pediatric models. Although studies showing improved functional recovery with treatments inhibiting apoptosis after cerebral ischemia suggest that some salvaged neurons regain their integrative properties, it is also possible that some of the delayed apoptosis represents appropriate pruning of neurons that have lost their targets. These processes, coupled with the need to restore highly integrated function, explain the clinical scenario of the persistent vegetative (minimally conscious) state despite restoration of normal function in other organ systems. The relationship of these distinct forms of cell death to selective vulnerability of neurons in brain is steadily increasing.

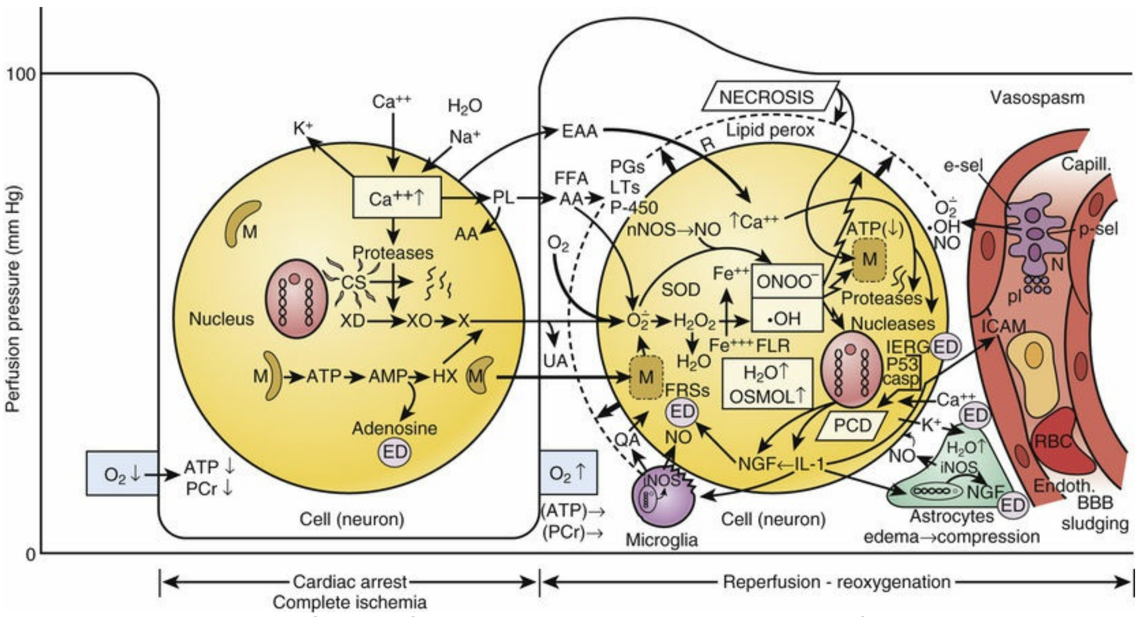

FIG. 68.2 Death of cells after temporary ischemia. Diagram of complex, partially hypothesized biochemical cascades in neurons during and after cardiac arrest.[77] Normally the intracellular ($[Ca^{2++}]i$) to extracellular ($[Ca^{2++}]e$) calcium gradient is 1 : 10,000. Calcium regulators include calcium/magnesium ATPase, the endoplasmic reticulum (ER), mitochondria, and arachidonic acid (*AA*). With stimulation, different cell types respond with an increase in $[Ca^{2++}]i$ because of the release of bound Ca^{2++} in the ER and influx of $[Ca^{2++}]e$ or both. During complete

ischemic anoxia (cardiac arrest) *(left),* the level of energy (phosphocreatinine [*Pcr*] and adenosine triphosphate [*ATP*]) decreases to near zero in all tissues at different rates, depending on stores of oxygen and substrate; it is fastest in the brain (~5 minutes) and slower in the heart and other vital organs. This energy loss causes membrane pump failure, which causes a shift of sodium (Na^+) ions, water (H_2O), and calcium ions (Ca^{2++}) from the extracellular into the intracellular space (cytosolic edema) and potassium (K^{++}) leakage from the intracellular into the extracellular space. Increase in $[Ca^{2++}]i$ activates phospholipase A_2, which breaks down membrane phospholipids (*PL*) into free fatty acids *(FFA),* particularly arachidonic (*AA*). Increase in $[Ca^{2++}]i$ also activates proteolytic enzymes, such as calpain, which may disrupt the cytoskeleton (*CS*) and possibly the nucleus. In mitochondria (*M*) hydrolysis of ATP to adenosine monophosphate (*AMP*) leads to an accumulation of hypoxanthine (*HX*). Increased $[Ca^{2++}]i$ may enhance conversion of xanthine dehydrogenase (*XD*) to xanthine oxidase (*XO*), priming the neuron for the production of the oxygen free radical superoxide anion ($O_2^{\dot{-}}$), although this pathway is of questionable importance in neurons (*X,* Xanthine; *UA,* uric acid). Excitatory amino acid neurotransmitters (*EAA*), particularly glutamate and aspartate, increase in extracellular fluid. Increased [EAA]*e* activates *N*-methyl-D-aspartate (NMDA) and non-NMDA receptors (*R*), thereby increasing calcium and sodium influx and mobilizing stores of $[Ca^{2++}]i$. Increased extracellular potassium activates EAA receptors by membrane depolarization. Glycolysis during hypoxia results in anaerobic metabolism and lactic acidosis, until all glucose is used (in the brain, during anoxia after ~20 minutes). This lactic acidosis, plus inability to wash out CO_2, results in mixed tissue acidosis that adversely influences neuronal viability. The net effect of acidosis on the cascades during and after ischemia is not clear. Mild acidosis may actually attenuate NMDA-mediated $[Ca^{2++}]i$ accumulation. Without reoxygenation, cells progress via first reversible, later irreversible structural damage, to necrosis at specific rates for different cell types. During reperfusion and reoxygenation *(right),* lactate and molecular breakdown products can create osmotic edema and rupture of organelles and mitochondria. Recovery of [ATP] and [Pcr] and of the ionic membrane pump may be hampered by hypoperfusion as a result of vasospasm, cell sludging, adhesion of neutrophils (granulocytes) (*N*), and capillary compression by swollen astrocytes, which also help to protect neurons by absorbing extracellular potassium. Capillary (blood-brain barrier [*BBB*]) leakage results in interstitial (vasogenic) edema. Increased concentrations of at least four oxyradical species that break down membranes and proteins, worsen the microcirculation, and possibly also damage the nucleus may be formed: Superoxide anion ($O_2^{\dot{-}}$) leading to hydroxyl radical ($\cdot OH$) (via the iron-catalyzed $Fe^{+++} \rightarrow Fe^{++}$, Haber-Weiss/Fenton reaction); free lipid radicals (*FLR*) and peroxynitrite ($OONO^{-}$). $O_2^{\dot{-}}$ may be formed from several sources: (1) directly from eicosanoid metabolism; (2) by the previously described XO system; (3) via quinone-mediated reactions within and outside the electron transport chain (from mitochondria [*M*]); and (4) by activation of NADPH-oxidase in accumulated neutrophils in the microvasculature or after diapedesis into tissue. Increased $O_2^{\dot{-}}$ leads to increased hydrogen peroxide (H_2O_2) production as a result of intracellular action of superoxide dismutase

(SOD). [H_2O_2] is controlled by intracellular catalase. Increased $O_2^{\cdot-}$ further leads to increased $\cdot OH$, because of conversion of H_2O_2 to $\cdot OH$ via the Haber-Weiss/Fenton reaction, with iron liberated from mitochondria. This reaction is promoted by acidosis. $\cdot OH$ and $OONO^{-}$ damage cellular lipids, proteins, and nucleic acids. Also, AA is metabolized by the cyclooxygenase pathways to prostaglandins (*PGs*) including thromboxane A_2, or by the lipoxygenase pathway to produce leukotrienes (*LTs*), and by the cytochrome P-450 pathway. These products can act as neurotransmitters and signal transducers in neuronal and glial cells and can activate thrombotic and inflammatory pathways in the microcirculation. Inflammatory reactions after ischemia have been shown to occur in extracerebral organs, focal brain ischemia, or brain trauma; to date, they have not been demonstrated after temporary complete global brain ischemia. Neuronal injury can signal interleukin-1 and other cytokines to be produced and trigger endogenous activation of microglia, with additional injury (*QA,* quinolinic acid). In addition, tissue or endothelial injury—particularly associated with necrosis—can signal the endothelium to produce adhesion molecules (intercellular [*ICAM*], e-selectin [e-sel], p-selectin [p-sel]), cytokines, chemokines, and other mediators, triggering local involvement of systemic inflammatory cells in an interaction between blood and damaged tissue. Reoxygenation restores [ATP] through oxidative phosphorylation, which may result in massive uptake of $[Ca^{2++}]i$ into mitochondria, which are swollen from increased osmolality. Thus mitochondria loaded with bound $[Ca^{2++}]$ may self-destruct by rupturing and releasing additional free radicals. Increased $[Ca^{2++}]i$ by itself and by triggering free radical reactions may result in lipid peroxidation, leaky membranes, and cell death. Neuronal damage can be caused, in part, by increased EAA (excitotoxicity). During reperfusion, $[Ca^{2+}]i$ and increased EAAs normalize. Their contribution to ultimate death of neurons is more likely through the cascades they have triggered during ischemia. During ischemia and subsequent reperfusion, loading of cells and calcium maldistribution in cells are believed to be the key trigger common to the development of cell death. This calcium loading signals a wide variety of pathologic processes. Proteases, lipases, and nucleases are activated, which may contribute to activation of genes or gene products (ie, caspases [*Casp*] or *P53*) critical to the development of programmed cell death (*PCD,* ie, apoptosis, autophagy, or regulated necrosis), or inactivation of genes or gene products normally inhibiting this process. Activation of nNOS by calcium can lead to production of NO, which can combine with superoxide to generate peroxynitrite ($OONO^{-}$). $OONO^-$ and $\cdot OH$ both can lead to DNA injury and PCD or protein and membrane peroxidation and necrosis, respectively. Nerve growth factor (*NGF*) nuclear immediate early response genes (*IERG*) such as heat shock protein, free radical scavengers (*FRSs*), adenosine, and other endogenous defenses (*ED*) may modulate the damage. (Designed in 1995 by P. Safar, MD, and P. Kochanek, MD, with input from N. Bircher, MD, and J. Severinghaus, MD.)

Reperfusion Injury

Reoxygenation and reperfusion are essential to recovery of any organ after ischemia. Experimental evidence suggests, however, that certain aspects of reperfusion result in tissue injury.[78,79] Reperfusion injury is a complex series of interactions between parenchyma and microcirculatory elements, resulting in detrimental effects that

negate some fraction of the benefits of reperfusion. The magnitude of reperfusion injury varies with the organ in question, the duration and type of hypoxic-ischemic insult, as well as the timing, duration, and magnitude of reperfusion.[80,81]

In the case of cardiac arrest, ischemia and reperfusion are global events. In the brain, early reperfusion (5–15 min) after asphyxia results in significant hyperemia.[82,83] In many organs and in the brain after focal insults, progressive microcirculatory failure is thought to be an important aspect of reperfusion injury.[84] However, as suggested by the nonspecific vascular distribution of selectively vulnerable neurons, the brain may display a second unique setting for the evolution of reperfusion injury, the evolution of selectively vulnerable cell death. Four key mechanisms hypothesized to be important to reperfusion injury in the brain include (1) excitotoxicity and calcium accumulation, (2) protease activation, (3) oxygen radical formation, and (4) membrane phospholipid hydrolysis and mediator formation.

Excitotoxicity and Calcium Accumulation

Glutamate and aspartate are the major excitatory amino acid neurotransmitters in the mammalian central nervous system (CNS), but both also have neurotoxic properties. Pioneering studies by Rothman and associates[85] demonstrated in vitro that hypoxia-induced neuronal death is mediated by synaptic activity. Inhibition of synaptic glutamate release or blockade of glutamate receptors prevented hypoxia-induced neuronal injury. Glutamate is the major neurotransmitter in the selectively vulnerable zones and accumulates extracellularly at supraphysiologic levels in these regions after hypoxic or ischemic insults.[38] In other regions asphyxia induces significant increases in dopamine, serotonin, norepinephrine, and gamma-aminobutyric acid [GABA], which are larger than the increases in glutamate in relative though not absolute concentrations.[21]

Glutamate is released at the presynaptic terminal in response to neuronal stimulation and acts by binding to postsynaptic dendritic receptors. Two main classes of excitatory neurotransmitter receptors have been identified. One class consists of the ligand-gated ion channels (“ionotropic” receptors) and includes *N*-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) or quisqualate, and kainate receptor subtypes. Toxicity caused by NMDA receptor activation is usually rapid, whereas AMPA or kainate receptor-mediated cell death is somewhat slower to develop.[86] Progress in NMDA receptor (NMDAR)–mediated neurotransmission has revealed greater complexity then previously appreciated—and may better inform therapy. NMDARs consist of heterodimeric glutamate receptor (GluR) subunits including NR1, NR2A, and NR2B. NR2A-containing NMDARs are enriched in the synapse (synaptic NMDARs), whereas NR2B-containing NMDARs are enriched at extrasynaptic sites (extrasynaptic NMDARs). Activation of synaptic NMDARs is neuroprotective. They increase nuclear calcium; activate cAMP-response element binding (CREB), brain-derived neurotrophic factor (BDNF), protein kinase B (PKB), and phosphorylated-JACOB (p-JACOB); and up-regulate antioxidants. In contrast, activation of extrasynaptic NMDARs by glutamate spillover in ischemia has the opposite effect. Extrasynaptic NMDARs increase cytoplasmic calcium; inhibit CREB, PKB, p-JACOB, and BDNF; activate calpain; stimulate death-associated protein kinase; and activate autophagy. Thus it appears that it is the extrasynaptic NMDARs that mediate

neuronal death. The other class of excitatory neurotransmitter receptors includes the metabotropic receptors, which are coupled with G proteins and modulate intracellular second messengers such as calcium, cyclic nucleotides, and inositol triphosphate.[87] When activated, the ionotropic glutamate receptors open sodium channels and may also initiate membrane depolarization and spreading depression.[88] With ionotropic receptor activation, rapid excitatory amino acid–mediated calcium accumulation occurs. In the face of ischemia this calcium accumulation is exacerbated by cellular energy failure, which disables the Na^+/K^+-ATPase membrane pump and results in further calcium accumulation.[38] Reestablishment of the energy supply can reverse these changes. Delayed glutamate-related neuronal injury is most likely the result of activation of ionotropic receptors and subsequent calcium influx. Calcium influx causes death of neurons in culture under anoxic conditions or in the presence of glutamate.[38] The intracellular accumulation of calcium (1) activates proteases, lipases, and endonucleases resulting in the breakdown of membrane phospholipids; (2) activates neuronal nitric oxide synthase (nNOS), resulting in nitric oxide (NO) production and, in the presence of superoxide, peroxynitrite formation; (3) damages mitochondria; (4) disrupts nucleic acid sequences; and (5) ultimately mediates cell death via necrosis, apoptosis, or autophagy (see Fig. 68.2). The disturbance of the finely regulated intracellular calcium homeostasis is now recognized as a possible final common pathway of neuronal death.[32,38,77,87] Related to this occurrence, studies suggest that novel approaches targeting calcium-calmodulin (CaM)–dependent protein kinase II (CaMKII) may have promise in protecting against neuronal death.[89] NMDA receptor activation has also been shown to stimulate superoxide anion production, which may contribute to cellular injury.[90] The NMDA and AMPA-receptor subtypes have been suggested to play key roles in ischemic brain injury. The potential implications of these mechanisms in regard to therapeutic manipulation of glutamate receptors, as well as calcium and sodium channels, are discussed later.

Protease Activation

One of the candidates for a critical role in neuronal injury as a result of increases in intracellular calcium concentration is protease activation. Protease activation plays a central role in mediating both necrosis and apoptosis. With regard to necrosis, numerous calcium-dependent enzymes can become activated during ischemia and produce important structural injury to neurons. One class of calcium-dependent proteases, calpains, are cytosolic cysteine proteases that have a homeostatic role in cell cycle regulation, differentiation, cell migration, and signal transduction.[91] After injury, calpain-mediated proteolysis of cytoskeletal proteins as well as activation of protein kinase C and phospholipases can occur.[91] Calpains also proteolyze the major plasma membrane sodium/calcium exchanger in neurons during excitotoxicity, allowing enormous secondary influx of calcium into the cell following extrasynaptic NMDA receptor activation and creating a positive feedback environment.[92] In a model of oxygen-glucose deprivation in neuronal cell culture that mimics transient ischemia, calpains induced mitochondrial release of AIF, which translocates to the nucleus to initiate caspase-independent apoptosis.[93]

With regard to apoptosis, the caspase family of cysteine proteases plays an important role after cerebral ischemia and may have a more prominent role in the developing versus mature mammalian brain.[94,95] After unilateral hypoxic-ischemic

brain injury, neonatal rats had increased cytochrome c release and caspase-3 activation versus juvenile and adult rats.[67] Regulation of apoptotic machinery also appears to be sex dependent after neonatal hypoxic-ischemic brain injury.[96] Comparatively, female rats had more caspase-mediated apoptosis, whereas male rats had more caspase-independent, AIF-mediated apoptosis.

Oxygen Radical Formation

Toxic oxygen radical species produced during postischemic reperfusion have been implicated as important contributors to reperfusion injury and delayed cell death.[79] The primary species of interest include superoxide anion, hydrogen peroxide, hydroxyl radical, and the reactive nitrogen species peroxynitrite. Very high, pathologic levels of free radical generation occur in brain early in reperfusion with resolution within the first hour.[97-99]

The potential sources of oxygen radicals are many. Two major sources of reactive oxygen species upon reperfusion include electron transport chain components and other proteins such as alpha-ketoglutarate dehydrogenase[100] in mitochondria and NADPH oxidase in the cytosol.[101] Superoxide anion is produced by the electron transport chain during normal mitochondrial respiration. Mitochondrial dysfunction, as may occur under conditions of ischemia, increases the generation of free radicals that may extend beyond the capacity of endogenous antioxidants leading to oxidative stress. Studies have revealed that oxidative stress linked to mitochondria after cardiac arrest and TBI is a highly orchestrated and seminal event in the evolution of oxidative damage, and that the process involves oxidation of the unique mitochondrial lipid cardiolipin by cytochrome c in the inner mitochondrial membrane via a calcium independent pathway.[102,103] Inhibition of this pathway with mitochondrial-targeted nitroxides has been shown to block this pathway and improve outcome specifically in preclinical models of asphyxial cardiac arrest.[103] Studies show that several NADPH oxidase isoforms (Nox1, Nox2, and Nox4) capable of generating significant amounts of superoxide and its dismutation product hydrogen peroxide are expressed in endothelium, neurons, glia, and microglia.[104] Superoxide generation upon stimulation of NMDA receptor can be blocked by the NADPH oxidase inhibitor apocynin and in neurons lacking the p47 (phox) subunit, which is required for NADPH oxidase assembly.[101]

Other sources of reactive oxygen species upon reperfusion may include (1) the cyclooxygenase, lipoxygenase, and cytochrome P-450 pathways, where metabolism of arachidonic may produce superoxide anion as an enzymatic byproduct[79,105]; (2) the xanthine oxidase (XO)[106,107] pathway (however, the importance of XO in contribution to the generation of free radicals in human beings remains unclear)[108,109]; (3) autoxidation of circulating catecholamines or of neurotransmitter catecholamines may represent another potential source of oxygen radicals; and (4) delocalized iron, normally transported in the blood tightly bound to transferrin and stored inside the cell bound to ferritin. In ischemic conditions with accompanying acidosis, however, iron may be displaced from its normal binding sites and can catalyze reactions that promote oxygen radical formation.[110,111] Most commonly implicated is the Haber-Weiss/Fenton reaction, whereby the potent hydroxyl radical is produced from superoxide anion and hydrogen peroxide in the presence of free iron. The iron-chelator, deferoxamine, has been shown to reduce neurologic injury after experimental neonatal hypoxia-ischemia[112,113]; and (5) NO is another free radical that

contributes to both nitrosative and oxidative stress. NO increases during ischemia via increased NMDA receptor stimulation, mediated by release of excitatory amino acids and subsequent calcium-mediated activation of nNOS.[114] NO in the presence of superoxide produces peroxynitrite.[115] However, NO can also serve as a potent antioxidant,[116] and beneficial effects of local release of NO and nitrosylation reactions may underlie promising effects of new therapies such as nitrite therapy or remote ischemic postconditioning.[117-119] Free radicals have also been associated directly with an increase release of excitatory amino acids and vice versa.[90,120] Not only do they participate in each other's release and formation but they may act synergistically in causing tissue damage.

The brain may be particularly vulnerable to free radical injury for several reasons. One is the high concentration of polyunsaturated fatty acids, especially arachidonic acid. Release of free fatty acids (FFAs) occurs throughout ischemia. On exposure to oxygen radical species, these FFAs are vulnerable to autocatalytic lipid peroxidation.[121] These free-radical–mediated nonspecific lipid peroxidation reactions are likely a minor contributor and more difficult to target therapeutically compared to enzyme-mediated catalytic lipid peroxidation reactions after reperfusion. Cerebrospinal fluid (CSF) has low concentrations of iron-binding proteins; therefore iron released from injured neurons or glia is likely to contribute to these peroxidation reactions. Byproducts of these reactions, for example, malondialdehyde and conjugated dienes, although nonspecific, have been used as markers of the extent of lipid peroxidation after brain injury (eg, the thiobarbiturate assay). Lipid peroxides accumulate in the selectively vulnerable zones during reperfusion after transient forebrain ischemia.[110,122] The peroxides do not accumulate during the ischemic period itself or in areas that are not reperfused and thus are implicated in reperfusion injury.[123]

Investigators have also detected oxidative damage to brain proteins after reperfusion.[123] Pyruvate dehydrogenase, a key mitochondrial matrix enzyme that converts pyruvate into acetyl-coenzyme A, undergoes oxidative protein modification after ischemia that impairs enzyme activity, possibly contributing to neuronal cell death,[124] and oxidative damage to DNA could also play a role.[125] Developmental and sex differences exist in terms of the degree of oxidative stress and amount and function of antioxidant enzymes after brain injury. In mice, glutathione and catalase activity in brain are higher in adult female versus male mice, and discrepancies become more exaggerated with age.[126] Furthermore, neurons from male rats have less capacity to replenish glutathione levels after cytotoxic stress in vitro and in vivo after asphyxial cardiac arrest.[127]

Membrane Phospholipid Hydrolysis and Mediator Formation

Membrane phospholipids modulate signaling cascades, affecting the development, differentiation, function, and repair of the CNS, functions that become dysregulated with ischemia and oxidative stress.[128] FFAs are released from neuronal membranes during ischemia, and the amount of FFA released is proportional to the duration of ischemia. FFA release continues to change in proportion to duration of ischemia after the completion of energy failure.[129] FFAs are released by two distinct but related processes. First, phosphatidyl inositol is hydrolyzed by phospholipase C with the production of diacylglycerol (DAG) and inositol phosphates.[130,131] Phospholipase C–mediated hydrolysis begins during the initial moments of the ischemic insult and is

related to neurotransmitter receptor stimulation. DAG is then hydrolyzed by lipases to FFAs, predominantly arachidonic and stearic acid. Second, other brain glycerophospholipids are hydrolyzed by phospholipase A_2, which is activated by increases in intracellular calcium concentration. The action of FFA release and metabolism is not a generalized process in the neuronal membrane but is concentrated in the synaptic regions and is thus related to excitotoxicity.[132] As previously discussed, oxidized FFAs can also be released from mitochondrial cardiolipin, and this calcium independent pathway, which is mediated by cytochrome c, has been shown to play an important role in preclinical models of pediatric asphyxial cardiac arrest.[103]

The FFAs released then have potential detrimental effects during the postischemic period by multiple mechanisms: (1) arachidonic acid metabolism via the cyclooxygenase pathway may contribute to oxygen radical production during reperfusion[105]; (2) FFAs and DAG directly increase membrane fluidity, inhibit ATPases, increase neurotransmitter release, and uncouple oxidative phosphorylation; (3) enzymatic oxidation of arachidonic acid during reperfusion by cyclooxygenase, lipoxygenase, or cytochrome P-450 produces a large number of bioactive lipids, including prostaglandins, thromboxanes, leukotrienes, and hydroxy fatty acids, many of which have detrimental effects (see Fig. 68.2); and (4) release of lipid mediators from oxidized cardiolipin by phospholipase $A_2\gamma$. Studies suggest that the cytochrome P-450 metabolite 20-hydroxyeicosatetraenoic acid (HETE) may play a role in producing cortical vasoconstriction after cardiac arrest, and inhibitors of the responsible enzyme are being investigated as a possible therapy for cardiac arrest.[133] This pathway also appears to play a role in the development of brain edema after cardiac arrest.

Endogenous Defenses

In response to the complex sequence of pathobiological events that evolve after brain injury, several endogenous neuroprotectants are produced, induced, or activated after ischemia, and their postulated or proved functions improve cell (specifically neuronal) survival in in vivo and in vitro models. The heat shock proteins are one family of candidate neuroprotectants that are highly conserved among biological species and are induced in cells after a variety of stimuli. Thermal stress is the classic example; however, any insult that damages protein structure, including ischemic[134] and TBI,[135] can produce a heat shock protein (Hsp) response. Simon and colleagues[134] showed that after global ischemia the 72 kDa Hsp72 is temporally expressed in a pattern that mirrors the pattern of selective vulnerability in the model, seen first in the CA_1 region of the hippocampus, followed by CA_3, cortex, and thalamus, and finally in the dentate granule cells. Hsp72 is also induced in both gray and white matter of piglets following mild and severe hypoxia.[136] The Hsps have generated major interest as potential neuroprotectants because their prior induction by a sublethal stress can afford protection from subsequent injury. Transient, subthreshold whole-body hyperthermia reduces subsequent ischemic brain injury in both adult[137] and neonatal rats.[138] Furthermore, exogenous Hsp72 reduces glutamate toxicity in neuronal cell cultures.[139] Importantly, overexpression of Hsp72 reduces ischemic damage and apoptosis after experimental stroke and global ischemia in vivo.[140-142]

Another potential mechanism for endogenous neuroprotection is the up-regulation of genes that inhibit apoptosis and augment neurogenesis. The mammalian gene bcl-2, a proto-oncogene, can block apoptosis[143] and perhaps necrosis as well.[144] The bcl-2 gene is expressed in neurons surviving both focal and global ischemia[145,146] and is reduced in degenerating neurons after cardiac arrest in rats.[147] Viral transfection of bcl-2 reduces infarction after focal ischemia,[148] and up-regulation of bcl-2 via ceramide administered 30 minutes after hypoxia-ischemia reduced the number of cells with DNA damage in immature rat brain.[149] Forced overexpression of the bcl-2 family member bcl-xL also reduces tissue damage after focal cerebral ischemia in adult rats.[150] After TBI in infants and children, CSF levels of bcl-2 are increased in patients that survive compared with those that die.[151] Finally, bcl-2 overexpression promotes neurogenesis in adult mice with and without ischemic injury.[152]

Adenosine is an endogenous biochemical mediator that may serve a protective role after cerebral ischemia, particularly early after injury. It may be produced from ATP breakdown or via the newly discovered 2,3 cAMP adenosine pathway that has been shown to exist in brain.[153] Adenosine is increased in brain tissue after experimental ischemia[154] and in response to hypoxia,[155] hypotension,[156] and hypoglycemia.[157] The release of adenosine after ischemia could afford neuroprotection by a combination of several mechanisms. When bound to A2-receptors, adenosine is a potent cerebrovasodilator and inhibits platelet activation and neutrophil function.[158] Bound to A1-receptors, adenosine reduces neuronal metabolism and excitatory amino acid release and stabilizes postsynaptic membranes.[158] Thus the beneficial effects of adenosine after cerebral ischemia include improved regional CBF, reduced local oxygen demand, attenuation of both excitotoxicity and calcium accumulation, and antiinflammatory and rheologic effects. Finally, adenosine agonists have been shown to improve survival of selectively vulnerable neurons after ischemia in many studies (reviewed in Rudolphi and coworkers[159]).

Clinical Pathophysiology

Cerebral Blood Flow and Metabolism After Resuscitation

The pioneering studies in which global CBF and cerebral metabolic rate for oxygen ($CMRO_2$) were measured in animal models of global ischemia or cardiac arrest focused on the early postresuscitation period. In their classic study, Snyder and colleagues[160] showed that after 15 minutes of global brain ischemia in dogs, CBF transiently increased to levels well above baseline (Fig. 68.3). Then, after 15 to 30 minutes, CBF progressively decreased to a level below normal for the remainder of the monitoring period (90 minutes). This pattern of early transient postischemic hyperemia and subsequent delayed postischemic hypoperfusion has been observed in many global cerebral ischemia models, including both VF and asphyxial arrest, although in adult VF there is some suggestion it is less prominent.[83,161-163] The levels of hyperemia and subsequent hypoperfusion vary in relation to the duration of the insult.[164] Although these phases of increased and decreased CBF characterize the net

global effect, regional CBF is often inhomogeneous, particularly during postischemic hypoperfusion, when areas of decreased and increased perfusion may coexist.[165] The ability of antioxidants to blunt reperfusion hyperemia suggests it may be the result of oxidative signaling involving the neurovascular bundle.[99,161]

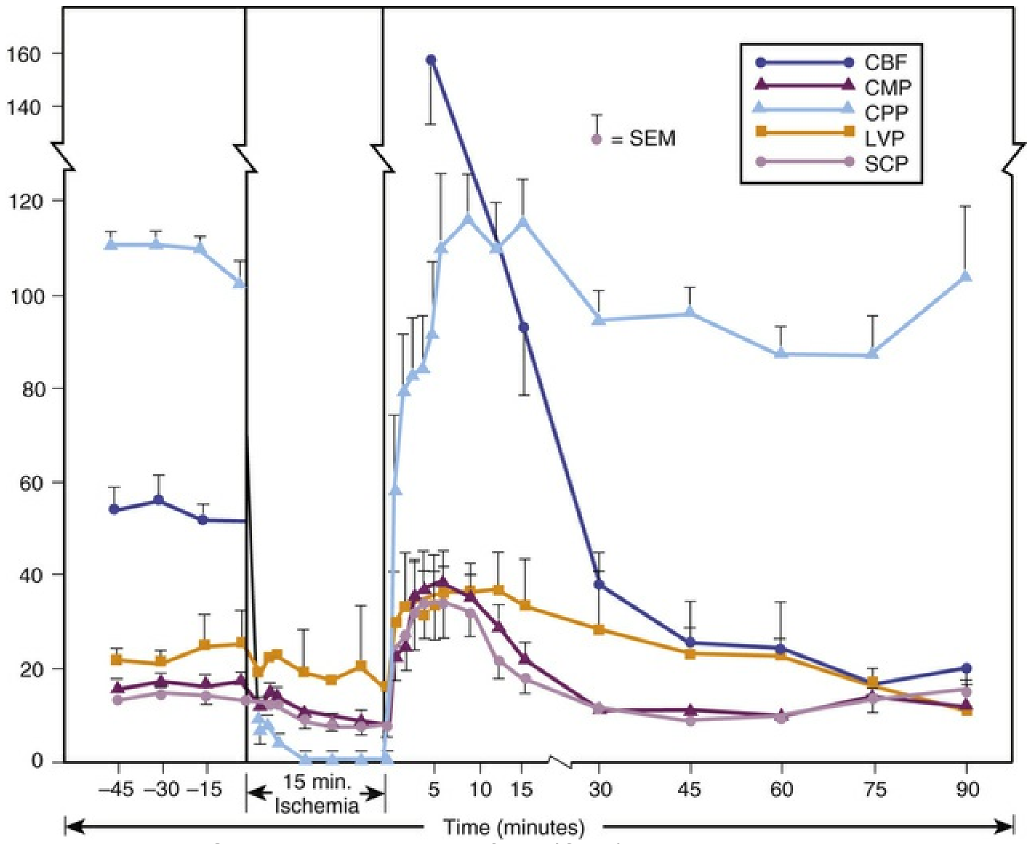

FIG. 68.3 Global cerebral blood flow *(CBF)*, cisterna magna pressure *(CMP)*, cerebral perfusion pressure *(CPP)*, lateral ventricular pressure *(LVP)*, and supracortical pressure *(SCP)* measured before, during, and for 90 minutes after a 15-minute circulatory arrest in dogs. CBF data demonstrate that early postresuscitation hyperemia occurs, followed by hypoperfusion. (Adapted from Snyder JV, Nemoto EM, Carroll RG, Safar P. Global ischemia in dogs: intracranial pressures, brain blood flow and metabolism. Stroke. 1975;6:21-27.)

The heterogeneous- and duration-dependent nature of postarrest CBF was characterized using contemporary imaging techniques allowing for regional assessment and a clinically relevant model of pediatric asphyxial cardiac arrest.[166] Using arterial spin labeling magnetic resonance imaging (MRI), CBF was measured for the first 3 hours after 8.5, 9, or 12 minutes of asphyxial cardiac arrest in postnatal day 17 rats—approximating a 1- to 4-year-old human in terms of brain development (refer to Chapter 60). Although the pattern of early global hyperemia followed by hypoperfusion similar to that observed by Snyder and associates[160] was seen after asphyxial arrests lasting 8.5 and 9 minutes, a pattern of global and persistent hypoperfusion was observed after a 12-minute arrest (Fig. 68.4). Remarkably, CBF disturbances were also found to be region dependent after asphyxial arrests lasting 8.5 and 9 minutes, with subcortical hyperemia but cortical hypoperfusion (see Fig. 68.4). After a 12-minute asphyxial arrest, hypoperfusion was observed in both

cortical and subcortical regions, and CBF was pressure-passive with epinephrine infusion, perhaps indicating loss of autoregulation after a prolonged arrest. This is consistent with descriptions of increased loss of neurovascular coupling with longer global ischemic durations.[167] In the same model using a 9-minute asphyxial arrest duration, intravenous (IV) infusion with polynitroxyl albumin, an antioxidant, during resuscitation decreased early (5-minute) hyperemia whereas albumin augmented and prolonged hyperemia. Both interventions led to improved spatial memory performance in male rats only.[82] The optimal CBF target postresuscitation is not known and may be brain region and time dependent.

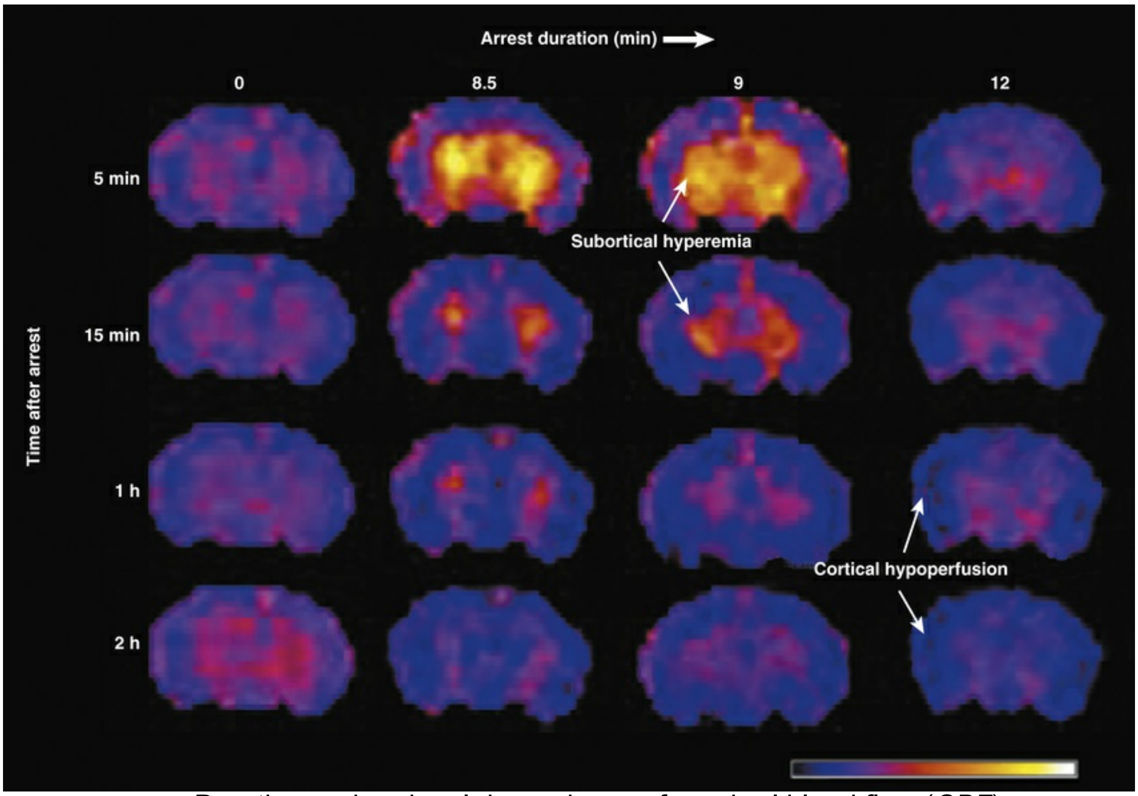

FIG. 68.4 Duration and regional dependency of cerebral blood flow (*CBF*) disturbances acutely after asphyxial cardiac arrest in postnatal day 17 rats. CBF data demonstrate that early postresuscitation hyperemia occurs in subcortical regions after an 8.5- and 9-minute but not a 12-minute asphyxial cardiac arrest and that duration-dependent hypoperfusion occurs in cortical regions. (Adapted from Manole MD, Foley LM, Hitchens TK, et al. Magnetic resonance imaging assessment of regional cerebral blood flow after asphyxial cardiac arrest in immature rats. J Cereb Blood Flow Metab. 2009;29:197-205.)

Invasive measurement of brain tissue oxygenation ($PbtO_2$) is a marker of local oxygen extraction fraction and surrogate marker of CBF. In the rat pediatric asphyxial cardiac arrest model, postresuscitation cortical $PbtO_2$ values decreased below baseline by 30 minutes and remained low at 2 hours. In contrast, significant hyperoxia was observed in the thalamus 5 minutes after ROSC, decreasing to normal values over 2 hours.[12] Notably, $PbtO_2$ was FiO_2 dose responsive in both brain regions. In a swine model of VF arrest, marked hyperoxia is observed in the cortex 15 minutes after ROSC using an FiO_2 of 1 and 1 hour after ROSC with reduced FiO2

to 0.5 (PbO_2 > 3× and 2× baseline, respectively).[168] It is unclear whether differences in postresuscitation PbO_2 seen in these two studies are related to differences between asphyxia and VF arrest, species, developmental age, injury severity, or any combination of these factors.

In patients with good outcomes, global CBF recovers over the subsequent 24 to 72 hours and CO_2 reactivity remains intact. Patients who do not regain consciousness or progress to brain death develop absolute or relative CBF hyperemia with impaired CO_2 reactivity.[169,170] A theoretic scheme of postarrest global CBF and its relation to neurologic outcome is presented in Fig. 68.5. Most studies in experimental animal models of asphyxial arrest suggest a similar pattern of CBF and $CMRO_2$ to that observed after VF cardiac arrest and global ischemia in the early postresuscitation period in humans.[162,169] However, there are some exceptions.[171] Results from clinical studies of pediatric asphyxial arrest are scarce and somewhat conflicting with regard to the prognostic implications of high or low values of postarrest CBF based on a single measurement; however, loss of CO_2 reactivity appears to be associated with poor outcome in all studies. In studies of children between 24 and 48 hours after near-drowning, Ashwal and colleagues[172] observed low CBF in the seven nonsurvivors and no relationship between CBF and $PaCO_2$ in these patients—again suggesting loss of CBF reactivity to changes in $PaCO_2$. In this study, hyperemia was not routinely observed in either survivors in a persistent vegetative state or children who died, but only a single CBF measurement was made in these patients. Beyda[173] obtained serial measurements of postarrest ^{133}Xenon in a series of children who suffered asphyxial arrest from submersion accidents. Children with good neurologic outcomes had slightly decreased CBF values at 12 hours that increased to normal during the subsequent 24 to 60 hours. In these children, CBF reactivity to CO_2 was intact. Children with eventual vegetative outcome or brain death exhibited hyperemia with loss or attenuation of CO_2 reactivity. This hyperemia progressed to low or normal flow over the following 12 to 72 hours in children with vegetative outcome and progressed to low and then no flow with the development of brain death. A pilot pediatric study found that time spent under the optimal mean arterial pressure range where autoregulation was present, based on an infrared cerebral oximetry-arterial pressure–based system, was predictive of poor outcomes.[174] Arterial spin labeling MRI techniques have been developed that do not require contrast material injections. In a small study that included both adults and children, global hyperemia was demonstrated after cardiac arrest at varying time points.[175] In neonates with HIE, hyperperfusion occurred in regions with concurrent water diffusion abnormalities, implying a potential pathophysiologic linkage between the two observations, but patient outcomes were not reported.[176]

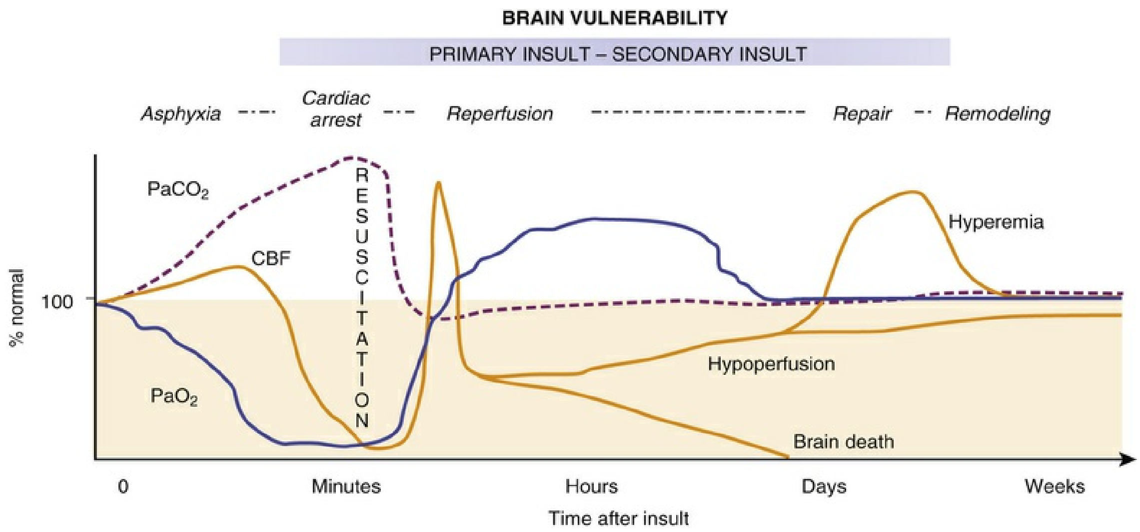

FIG. 68.5 Hypothetical diagram illustrating the patterns of *global* cerebral blood flow *(CBF)* during and after cardiac arrest of moderate duration in humans. Immediately after resuscitation, "early postischemic hyperemia" occurs for about 15 minutes in subcortical brain regions. This is followed by patchy multifocal "delayed postischemic hypoperfusion" in cortical brain regions lasting from a few hours to days. Progressive return of CBF to normal is seen in patients with intact neurologic outcome. In contrast, "delayed postischemic hyperemia" can be observed hours to days postarrest in patients with more severe insults.[170,173] This delayed hyperemia appears to be associated with disabled or vegetative outcome (where CBF gradually decreases to near normal or below normal) or brain death (where CBF decreases to no flow). It is unclear, however, if all patients with vegetative outcome or eventual brain death develop delayed hyperemia.

Brain metabolism, as assessed by $CMRO_2$, is reduced during the early postischemic period and then progressively recovers to a level that varies, depending on the model used and on the duration of ischemia.[164,177] In some models, including VF arrest in dogs, significant recovery of $CMRO_2$ may occur during the first few hours, despite persistent postischemic hypoperfusion—creating the potential for a secondary ischemic insult during reperfusion. Whether this increase in $CMRO_2$ represents appropriate synaptic activity, seizures, or basal metabolism is not certain. In other models and in descriptions of adult cardiac arrest, global CBF and $CMRO_2$ were matched during the first few hours after ischemia with delayed relative global hyperperfusion.[169]

Cerebral microdialysis has been used in pilot studies to assess for alterations in metabolism after cardiac arrest. Using microdialysis in a porcine model of cardiac arrest, increased lactate/pyruvate ratios were found during arrest and again in a delayed fashion especially if kept normothermic versus hypothermic.[178] This same group found increased lactate/pyruvate ratios and glutamate using microdialysis in adult survivors after cardiac arrest, all of whom were treated with hypothermia.[179] Prolonged increases in brain lactate detected using proton MRS after global hypoxia-ischemia in children have also been reported.[35,180,181] Oxidative stress decreases the function of the pyruvate dehydrogenase complex, a key enzyme in oxidative metabolism, possibly contributing to the shift to anaerobic metabolism.[182] Although

routine monitoring of CBF, CMR, or $PbtO_2$ has not been applied extensively to the postarrest setting in children, their routine assessment using contemporary methods may possibly lead to an improved understanding of pathophysiology.

Drugs such as nimodipine can increase CBF during the early postischemic hypoperfusion phase after global cerebral ischemia, though outcomes were not affected.[183] $CMRO_2$ recovery generally is not affected by treatment.[184] The testing of strategies targeting early postarrest hypoperfusion deserves further study. Safar and coworkers[185] have reported that a multifaceted treatment strategy to increase CBF ("flow promotion") and reduce CMR or $CMRO_2$ early after VF in dogs improved outcome. This was accomplished by use of cardiac bypass (CPB), mild hypothermia, hemodilution, and transient hypertension. However, more selective therapies may be needed, and potential agents targeting CBF currently being explored, as previously stated, include nitrite, remote ischemic postconditioning, and 20-HETE inhibitors, among others.

An important limitation in all existing studies on CBF/$CMRO_2$ is that the spatial resolution of the techniques used (positron emission tomography [PET], Xe CT, MRI) permits examination of regional CBF heterogeneity but does not resolve to the level of the microcirculation. At this level, studies using two photon microscopy have yielded important findings. First, a microvascular no-reflow phenomenon may be present on the basis of pericyte contraction, with ischemia and cell death that is not amenable to increasing cerebral perfusion pressure.[186] Second, microvascular shunts at the level of small arterioles may redirect blood flow toward or away from capillary beds with either beneficial or detrimental effects on microcirculatory flow, respectively.[187] The implication of these findings is that cerebral perfusion pressure though adequate as a measure of global CBF may not provide adequate perfusion on the microcirculatory level due to these issues. At present the only clinically useful method to detect such disturbance would be microdialysis, which is limited to only a small area of tissue interrogation.

Histopathology of Hypoxic-Ischemic Encephalopathy

Ischemic neuronal change (Fig. 68.6), as first described by Sommer in 1880 and later by Spielmeyer, involves a progression from extensive cellular microvacuolation to a cell that resembles a naked shrunken nucleus.[25] As described by Brierley and colleagues,[44] "this type of neuronal damage is neither ubiquitous nor randomly distributed but is found in regions which exhibit selective vulnerability to hypoxic stress." As discussed previously, death of selectively vulnerable neurons (eg, hippocampal CA_1) cannot be explained by vascular distribution. Remarkably, these clinical descriptions of cell shrinkage were consistent with apoptosis rather than necrosis. However, the connection between selective vulnerability and apoptosis was made 100 years later.[56] Neuronal death after cardiac arrest is seen not only in the selectively vulnerable neurons but also as a subtle histopathologic finding in the arterial boundary zones. These neurons (not otherwise selectively vulnerable) are in the most poorly perfused areas during or after resuscitation.[41] Neuronal death in the arterial boundary zones was elegantly described by Nemoto and associates in a monkey model of 16 minutes of complete global brain ischemia followed by 7 days of intensive care.[188] Maximal damage appeared to be in the classically described

selectively vulnerable zones, but neuronal death was also observed in the most distal distribution of the posterior cerebral artery and in the watershed zones of the anterior and middle cerebral arteries (Fig. 68.7). With sufficient injury in the arterial boundary zone, more severe findings such as microinfarction or laminar necrosis can be seen.[26,188] As previously discussed, even in stroke, neuronal death in an ischemic penumbra can occur either by necrosis or apoptosis. Thus it appears that there may be a continuum between apoptosis and necrosis that may depend on a large number of factors, such as duration of the insult and brain region in question.[73] Whereas apoptosis in a given area often affects only a select percentage of neurons, infarction affects all neurons and glia. Obviously, if the arrest time is long or if the postischemic conditions are sufficiently poor, infarction of the entire brain can occur.

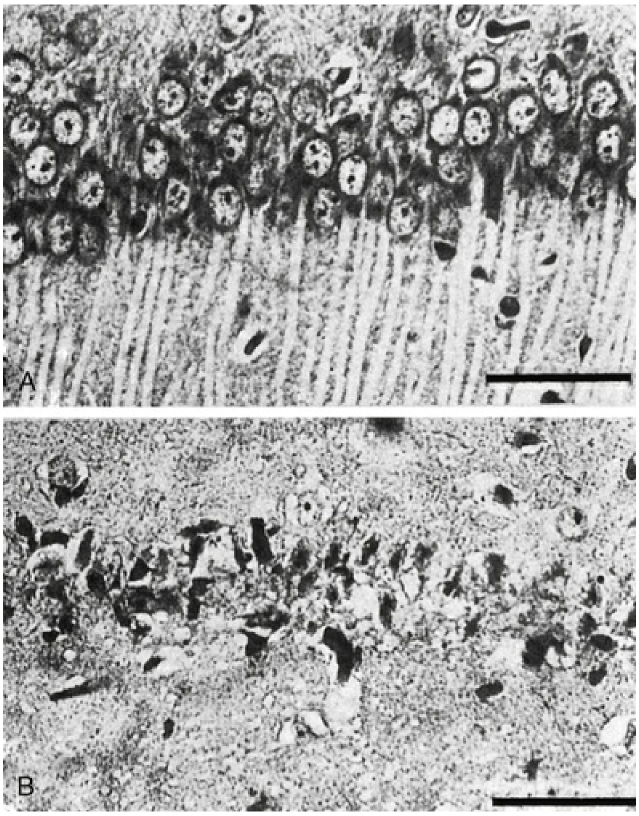

FIG. 68.6 Light micrograph of dorsal hippocampus in gerbils 7 days after 5 minutes of sham ischemia (A) or global ischemia by carotid occlusion (B). Ischemic neuronal change is seen with CA_1 neurons appearing as dark, shrunken nuclei without cytoplasm (B) by contrast with the normal-appearing nonischemic neurons (A). Investigations by Nitatori and colleagues[56] indicate that neuronal death in selective areas, after threshold ischemia insults, occurs via apoptosis. (From Kuroiwa T, Bonnekoh P, Hossmann KA. Therapeutic window of CA1 neuronal damage defined by an ultrashort-acting barbiturate after brain ischemia in gerbils. Stroke. 1990;21:1489-1493.)

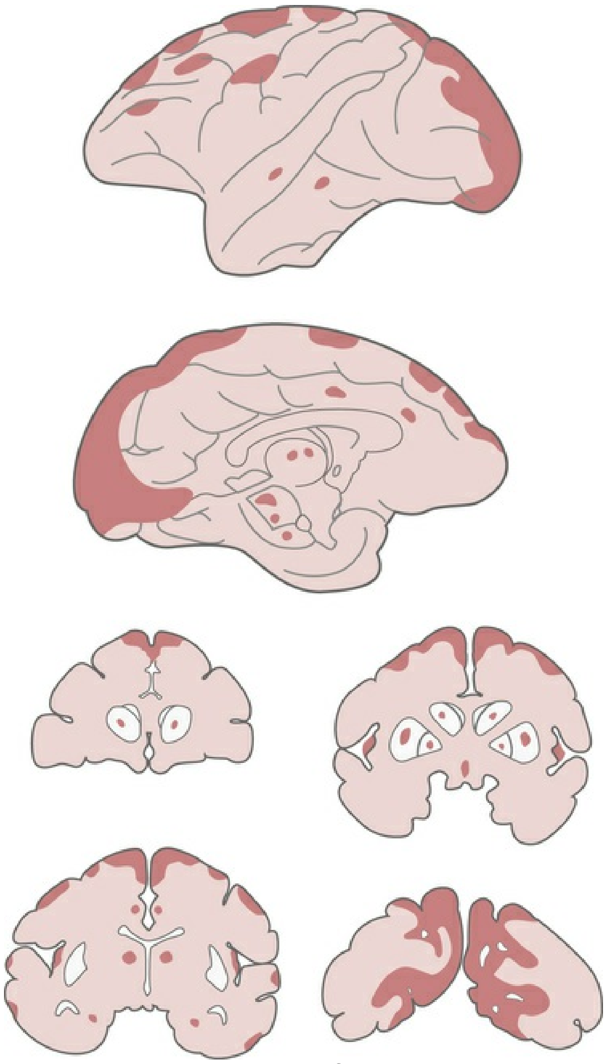

FIG. 68.7 Topographic distribution of cortical lesions 7 days after 16 minutes of global brain ischemia in rhesus monkeys. Neuronal death in areas with intrinsic selective vulnerability was most apparent in the distal distribution of the posterior cerebral artery. Damage in the watershed distributions of the anterior and middle cerebral arteries was less consistent. (Adapted from Nemoto EM, Bleyaert AL, Stezoski SW, Moossy J, Rao GR, Safar P. Global brain ischemia: a reproducible monkey model. Stroke. 1977;8:558-564.)

Vaagenes and colleagues studied neuropathology after primary VF arrest of 10 minutes in dogs.[26] Despite vegetative outcome at 96 hours, only scattered ischemic neuronal changes in the selectively vulnerable neurons and to a much lesser extent in the vascular watersheds were observed. Microinfarct formation was seen in only 5 of 18 dogs, suggesting that patchy ischemic neuronal change is sufficient for vegetative outcome. They then compared this 10-minute VF arrest with an asphyxial episode (airway occlusion) resulting in cardiac arrest with 7 minutes of no flow. Related either to differences in the initial insult or to postischemic events, asphyxial arrest resulted not only in ischemic neuronal change in the selectively vulnerable regions but also in marked microinfarct formation (30 of 32 dogs) and scattered petechial hemorrhages. This more severe histologic injury was seen despite significantly *easier* ROSC in the asphyxial arrest group (Fig. 68.8). In addition, unlike VF arrest, asphyxial arrest caused some ischemic neuronal changes even after no

flow of only 2 minutes. These findings may explain the poor outcome generally observed in cardiac arrest in children (usually asphyxial arrest) compared with that in adult series (VF arrest). After asphyxial cardiac arrest that results in long-term survival in both adult and pediatric-aged animals,[189-191] the pattern of neuronal death produced is similar to that reported in human studies[192] including that of the young victim of asphyxial cardiac arrest, Karen Ann Quinlan,[193] where a predilection for basal ganglia injury resulting in a persistent vegetative state is observed. Finally, studies by Hogler and associates[194] demonstrated the expansion of damage comparing 7 versus 10 minutes of VF cardiac arrest in pigs. Substantial expansion of neuronal death across multiple brain structures such as cortex, caudate, and cerebellum was seen between the 7- and 10-minute durations, and edema appeared in the 10-minute group. These studies shed additional light on the impact of cardiac arrest duration on the extent of neuronal damage, given the challenges of defining arrest duration in the human condition.

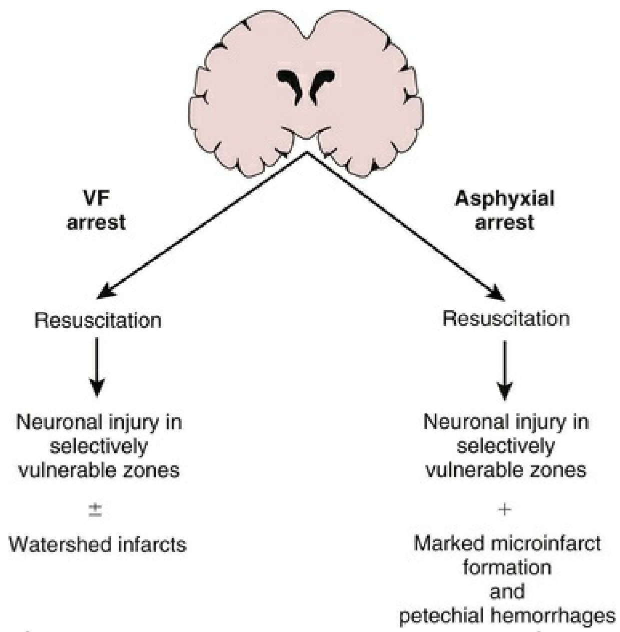

FIG. 68.8 Schematic diagram based on the work of Vaagenes and colleagues[26] comparing the histologic outcome of VF cardiac (adult) and asphyxial (pediatric) arrest. (From Kochanek PM. Novel pharmacologic approaches to brain resuscitation after cardiorespiratory arrest in the pediatric patient. In Holbrook P, ed. Critical Care Clinics. Philadelphia: W.B. Saunders; 1988:661-777.)

Clinical Outcome After Pediatric Cardiac Arrest

Survival and neurologic outcome after cardiac arrest in infants and children are remarkably poor.[8] One review summarizing the results from 44 studies totaling 3094 pediatric patients after cardiac arrest showed survival at hospital discharge in only 13% of patients, 8% for out-of-hospital and 24% for in-hospital cardiac arrest, respectively.[19] Survival to hospital discharge after out-of-hospital arrest ranges from 8% to 25% and after in-patient arrest is 24% to 51% in several studies, with an overall survival of 13%.[9,15,16,19,22] However, if the child had a pulse by hospital arrival after

out-of-hospital cardiac arrest, survival increases to 38%.[9] The most common cause of death is neurologic injury for out-of-hospital arrests and cardiovascular failure for in-hospital arrests.[9] Although survival to hospital discharge is higher in pediatric than adult cardiac arrest, the proportion of patients with good neurologic outcomes is lower, which may reflect in part lesser limitations of life-sustaining therapies in children compared to adults.[22] Good neurologic outcome in pediatric patients surviving cardiac arrest is often overestimated using traditional categorical outcome measures such as the Glasgow Outcome Scale score and Pediatric Cerebral Performance Category Scale.[195-197] Furthermore, contemporary longer-term outcome studies evaluating overall functional status, neuropsychologic function, and quality of life do not exist. One observational study focusing on late improvements in functional outcome noted improved mobility in 22% of children after cardiac arrest versus 66% of children after TBI 2 years after the initial event.[198]

High mortality and poor outcome after cardiac arrest in children generally represent out-of-hospital or unwitnessed cardiac arrests. The outcomes are worst in infants and preschool children where the proportion of witnessed arrests, bystander CPR, and nonasphyxial arrests are the lowest.[23,199] Recovery is much better in children who had witnessed arrests, cold water submersion, or isolated respiratory arrest, after which intact survival rates as high as 44% to 75% have been reported.[9,18,200-202] Nevertheless, these clinical data seem to bear out the severe neuropathology observed in asphyxia-induced arrest in animal models because asphyxial arrest is the most common mode of arrest in all of the clinical pediatric series.[18,19,195,200-202]

Clinical factors such as initial pH, number of epinephrine doses, and arrest duration have been examined in an attempt to prognosticate outcome from cardiac arrest. Although sometimes predictive, this information can be misleading. For example, the time delay before analysis of the first blood sample can vary, as can estimates of arrest duration. With asphyxial arrest, even controlled experimental animal studies show that the time from asphyxia until cardiac arrest varies considerably. Currently, the most powerful individual predictor of neurologic outcome after cardiac arrest is the neurologic examination.[203] As noted in one review, abnormal pupillary reactivity and motor response after 24 hours postcardiac arrest in the absence of sedation and muscle relaxation medications are useful for prognostication.[204]

The electroencephalogram (EEG) can also provide prognostic information for patients after cardiac arrest. Scollo-Lavizzari and Bassetti[205] retrospectively examined the relation between first postarrest EEG and clinical outcome in 408 cases. A five-grade classification was used to categorize EEGs. Although permanent severe neurologic damage was observed in some patients with grade I EEG, none of the 208 patients with grade IV or V EEGs had a good neurologic recovery. A single-center retrospective case series in children showed that having a burst suppression or electrocerebral silence pattern was associated with poor outcome at hospital discharge, with a positive predictive value of 90% and negative predictive value of 91%.[206] In children who underwent hypothermia postarrest, seizures were common, largely nonconvulsive, and occurred most frequently during the rewarming period.[207] Detailed quantitative EEG may also have a role in the prediction of neurologic outcome after cardiac arrest.[208] EEG reactivity may be an important prognostic tool after cardiac arrest in children.[209]

Adjunctive prognostic information also can be derived from brain-derived protein levels in serum or CSF. Serum brain biomarker trajectories, including S100b (from astrocytes), neuron specific enolase (NSE, from neurons), and myelin basic protein (MBP, from myelin), were noted to differ by brain insult.[210] Biomarker levels peaked earlier after accidental TBI, later after hypoxia, and were in-between for children with abusive head trauma. Two single-center prospective studies in children with cardiac arrest found that serum S100b and NSE had excellent prognostication accuracy.[211,212] NSE and other biomarkers may be useful in determining responsiveness to therapeutic interventions—that is, it has been reported that decreasing serum NSE occurs mainly in hypothermic (versus normothermic) adults after cardiac arrest and is predictive of outcome.[213]

Studies have used somatosensory-evoked potentials (SSEPs) in an attempt to provide early prognostic information about outcome after cardiac arrest resuscitation. Madl and colleagues tested median nerve SSEP in 66 adults after successful resuscitation from cardiac arrest. They reported that the presence or absence and the latency of the cortical N70 peak reliably differentiated between bad and favorable outcome with 100% predictive ability.[214] Testing was performed within 48 hours of resuscitation, which is a clinically relevant time frame. Auditory-evoked response testing has been used in children with cardiac arrest after a submersion accident.[215] Normal evoked responses were observed in all children who recovered neurologically intact. Children who recovered with significant handicaps demonstrated a reduction in wave V amplitude over time and prolonged wave I-V interpeak latencies. In adults, bilaterally absent N20 waves at 24 and 48 hours have a reported specificity of 100% in predicting poor outcome after cardiac arrest, but note that in many studies the SSEP results were used to guide medical decision making.[216] Summary recommendations from Abend and coworkers have suggested that the absence of bilateral cortical SSEPs are most reliably predictive of outcome when peripheral SSEP responses are present.[203]

The prospective utility of computed tomography (CT) of the head and other neuroimaging modalities after cardiac arrest is unknown (Fig. 68.9). Head CT takes only a few minutes and is useful for ruling out intracranial lesions contributing to the cause of arrest. In a large retrospective case series of children with near-drowning experiences, children with any abnormal CT finding (eg, loss of gray-white differentiation, infarction) within the first 24 hours of admission died.[217] Ninety-six percent of children with an initially normal CT on the first day who had a subsequent abnormal CT either died or remained in a coma. A new single-center retrospective study in children with cardiac arrest and brain CT within 24 hours found that loss of gray-white differentiation and basilar cistern effacement were associated with unfavorable outcomes.[218]

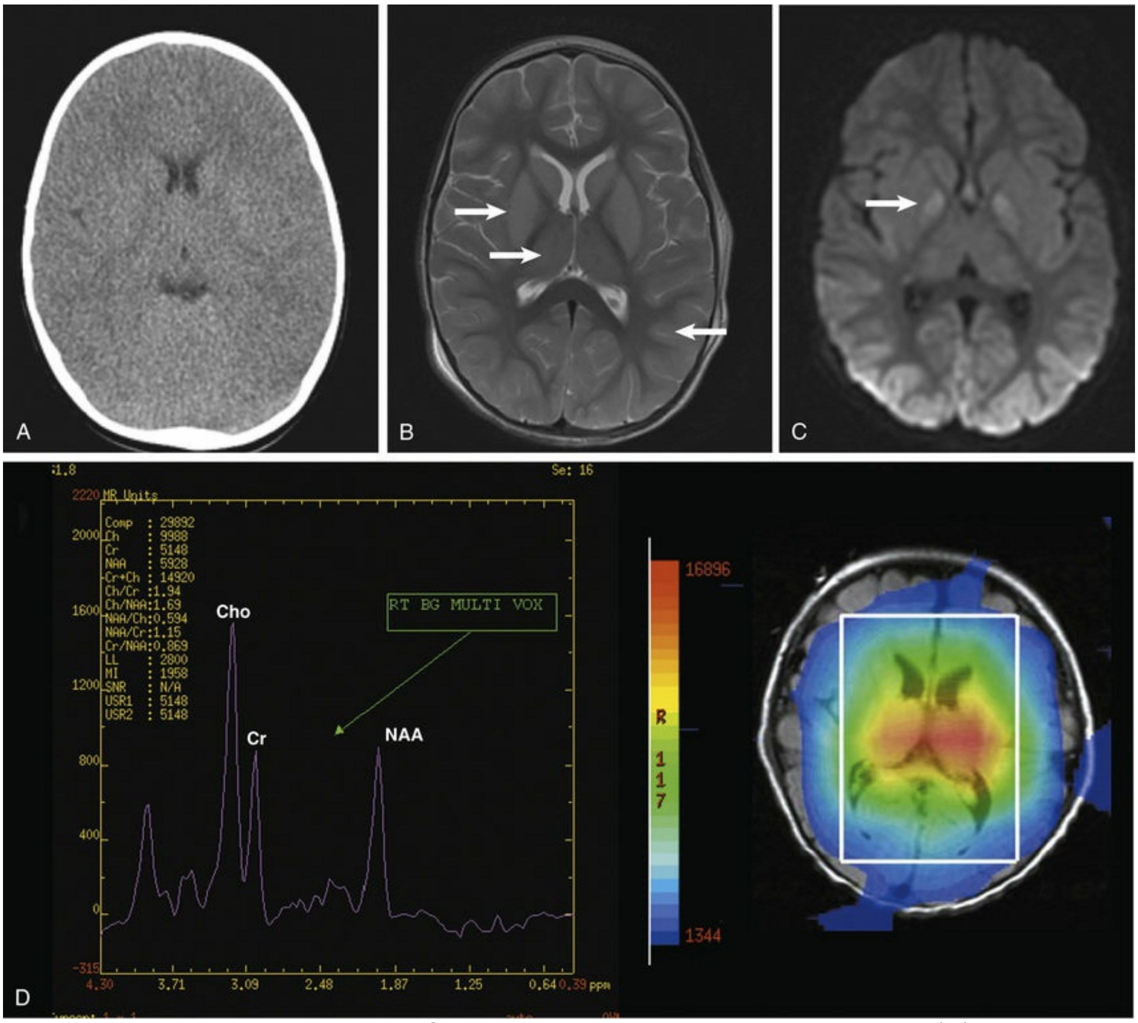

FIG. 68.9 Neuroimaging after asphyxial cardiac arrest in children. (A) Computerized tomography scan of the head on day 1 showing decreased gray-white differentiation, consistent with cerebral edema. (B) T2-weighted magnetic resonance image using a 3-Tesla magnet on day 10 showing enhancement of the basal ganglia, thalamus, and parietal lobes *(arrows).* (C) Diffusion-weighted imaging shows corresponding edema of the globus pallidus *(arrow).* (D) Multivoxel magnetic resonance spectroscopy showing the whole brain chemical analysis of *N*-acetylaspartate (*NAA*), choline (*Cho*), and Creatine (*Cr*). A regional color map for NAA is provided.

Brain MRI can provide excellent regional evidence of brain injury after cardiac arrest without radiation, but it requires long transports outside of the ICU. It is typically employed for prognostication subacutely after the patient stabilizes, but findings evolve over time. In one study that utilized a novel scoring system, damage seen in the cortex and basal ganglia correlated well with neurologic outcome.[219] Cortical lobe abnormalities in diffusion-weighted imaging and injury to the basal ganglia on conventional MRI were predictive of unfavorable outcome after pediatric cardiac arrest.[220] Using brain MRS, decreases in the brain metabolite *N*-acetylaspartate and increases in lactate in the basal ganglia and cortex can assist in outcome determination in children after near drowning and cardiac arrest.[180,221,222]

However, no one test or clinical variable will have sufficient accuracy to prognosticate on its own. Combining clinical variables with testing results improves

accuracy of outcome prediction.[223,224] Development and prospective validation of tests and panels of tests obtained early after cardiac arrest, that reliably predict ultimate outcome, would be valuable.

Response of the Immature Brain to Cardiac Arrest

Clinical and laboratory studies suggest that the neurologic outcome of newborn animals after a hypoxic-ischemic insult is favorable compared with that of adults, although this may be related to the ability of newborn animals to tolerate asphyxia systemically. This is most evident when neonatal and adult experimental models are compared. In newborn monkeys, even 12 minutes of asphyxia did not result in cardiac arrest,[225] and in beagle pups, 15 minutes of asphyxia produced hypotension but not cardiac arrest.[226] Asphyxial arrest in mature large animal models generally occurs within 6 to 8 minutes.[26,161] Kirsch and associates[227] showed that newborn piglets had better recovery of SSEP and less postarrest hypoperfusion than young adult pigs in the 2 hours after global cerebral ischemia. Thus not only does the cardiovascular response during asphyxia appear to be more robust in immature animals but also the intrinsic sensitivity of the brain to a hypoxic-ischemic insult may be less. Studies suggest a selective vulnerability of the neonatal brain stem sensory nuclei to asphyxia.[225,228] This selective vulnerability may more correctly represent a relative lack of vulnerability of neonatal cerebral cortex to asphyxia because anoxic perfusion was tolerated for over 12 minutes in immature monkeys, most of which demonstrated no ischemic neuronal change.[225] However, some mechanisms of secondary damage, such as excitotoxicity, appear to be more injurious in the immature.[229,230] Further complexity is added to processes such as excitoxicity when the immature brain is involved, as some degree of excitatory stimulation is essential for neuronal survival and normal development.[231] That fact may underscore the recognized vulnerability of developing neurons to sustained (6–8 hours or longer) exposure to certain anesthetics—a process that occurs in developing primates.[232] Finally, greater plasticity in the immature brain may also allow for improved long-term recovery of function, although this may be more important in focal insults.[233,234]

The poor clinical outcome of infants and children presenting in cardiac arrest is probably more related to specific mechanisms operating in the special setting of the asphyxial arrest. As the asphyxial arrest is developing, cardiac standstill is preceded by a variable period of severe hypoxia with increased CBF. During this period, severely hypoxic perfusion, a form of incomplete ischemia is produced, which can markedly increase cerebral lactate production.[235] The initial phase of asphyxia can also be accompanied by extreme stress during struggling, which could increase $CMRO_2$ and may be accompanied by systemic hyperglycemia.[172] The combination of hypoxic perfusion or incomplete hypoxia-ischemia and hyperglycemia can increase cerebral lactate concentration to 30 to 35 μmol/g and decrease tissue pH to levels as low as 6.05.[236-238] These lactate levels are much higher than those observed during even 30 minutes of complete ischemia (11 to 14 μmol/g) and are above the threshold of 20 to 25 μmol/g, at which lactic acid can produce local coagulation necrosis.[239] In addition, it has been shown that a veritable storm of neurotransmitters is released to

extremely high levels during the asphyxiation prior to reperfusion.[21] Thus the no-flow period in asphyxial cardiac arrest—in contrast to VF—is occurring in a brain that is already in a severely biochemically compromised state. As suggested by the histopathologic outcome studies previously discussed,[26] cardiac arrest or reperfusion may be particularly devastating to the brain in this milieu. Also, because of the relative resistance of the immature myocardium to asphyxia, it is easier to restore cardiovascular function in younger patients after longer durations of cardiac arrest than would be possible in adults. Total insult time (hypoxia plus anoxia plus cardiac arrest) is often very long. In adults with asystole or a pulseless bradycardia rather than VF, outcome is also poor.[240] Thus although pediatric intensivists have the apparent luxury of dealing with a somewhat resistant and more resilient brain, with capacity for plasticity, this advantage is often trivial compared to the devastating pathobiology of the asphyxial arrest.[191,241]

Treatment of Cardiac Arrest

Adequate understanding of the pathobiology of HIE after cardiac arrest in children is possible given the development of contemporary models of pediatric asphyxial arrest. These models will hopefully lead to more etiology-specific evaluation of the postresuscitation syndrome in terms of mechanisms and relevant therapies.[190,191] Prospective study of clinical targets for supportive postresuscitation care to optimize outcomes is vital.

Field Interventions

Pediatric cardiac arrests are usually not sudden in onset as in adults, and thus a window of opportunity exists during which interventions could potentially prevent cardiac arrest and subsequent poor outcome. As discussed, children sustaining isolated respiratory arrest have a mortality rate as low as 25%, whereas patients with cardiac arrests as a result of hypoxemia have a high mortality.[8,19] Thus the sooner the recognition and interventions, the better are the chances for a good outcome. Aside from witnesses with knowledge of CPR or the capacity to follow instructions provided by telephone emergency services, prehospital emergency medical services (EMS) are capable of providing the earliest medical interventions and hold the greatest promise for improving outcome from prehospital pediatric cardiac arrest. Emergency medical services have developed sophisticated methods for dispatch and transport, but there are logistical limits to the rapidity with which they can provide basic interventions. Nationwide the average response time is well over 8 minutes, greater than the time required for an infant to progress from apnea to cardiac arrest. As a result, more advanced, traditionally hospital-based, and investigational interventions must also be administered in the prehospital setting in attempts to optimize outcome. Toward this end, use of medical simulation has greatly improved both the understanding of the mechanics of quality CPR as well as teaching and training (see also Chapters 41 and 42).

Intracranial Pressure Interventions

Controlled experimental or prospective clinical studies of intracranial pressure (ICP)

monitoring or treatment after asphyxial arrest have not been performed. It could be predicted that ICP elevation would be more common after asphyxial arrest than after isolated global brain ischemia or VF arrest, given the severe histopathology seen after asphyxial arrest and the long insult times from which the myocardium can recover in children. Sustained elevation of ICP (>20 mm Hg) has been shown uniformly to predict poor outcome in four series of pediatric submersion accidents.[242-245] Unfortunately, as in VF arrest, the threshold for poor outcome from asphyxial arrest appears to be below the threshold for the occurrence of intracranial hypertension because some patients experience poor outcome despite normal ICP.[245] Although anecdotal cases of asphyxial arrest in patients with intact neurologic outcome despite elevated ICP are occasionally discussed, in the series cited previously the ability to control ICP elevation did not result in meaningful survival.[243,245] Routine ICP monitoring and ICP-directed treatment are not currently recommended after asphyxial arrest[243,245,246]; however, studies using ICP-directed therapy in the era of contemporary neurointensive care have yet to be performed.

The use of hyperventilation for cerebral resuscitation after cardiac arrest is currently out of favor. Only one laboratory study of cardiac arrest has demonstrated a beneficial effect of hyperventilation. Vanicky and colleagues[247] reported that 8 hours of hyperventilation reduced neuronal damage after cardiac arrest in dogs. However, histology was examined at 3 hours after arrest, and no long-term outcome was studied. The blind application of hyperventilation early after severe TBI in adults worsened outcome.[248] The failure of ICP-directed therapy to improve outcome after cardiac arrest and the commonly observed period of hypoperfusion in the first hours to days after arrest seriously question the application of an intervention with the potential to further reduce CBF.[249,250] Although irreversible ischemic brain damage has never been demonstrated with hyperventilation,[251] these data suggest that it is probably not wise to intentionally or unintentionally hyperventilate patients routinely after arrest, particularly during the period of postischemic hypoperfusion.[160,173,188] Clinical studies suggest that postischemic hyperemia is accompanied by loss or severe attenuation of the CBF response to alterations in $PaCO_2$ resulting from severe ischemic insult.[170,173] However, some postresuscitation patients with delayed hyperemia but intact CBF response to $PaCO_2$ have been observed (Fig. 68.10).

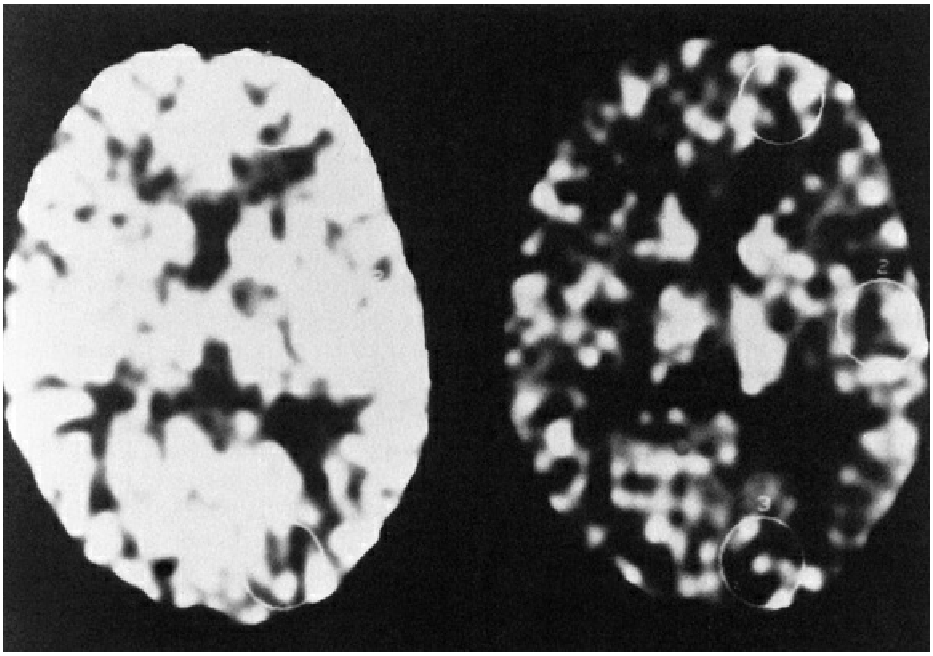

FIG. 68.10 Stable-xenon CT cerebral blood flow study in a comatose 6-year-old 3 days after cold-water submersion accident with asphyxial cardiac arrest. Delayed CBF hyperemia is represented as high-density white areas through the CT brain section shown on the left ($PaCO_2$ ~40 mm Hg). Flows (calculated from this scan) are in excess of 100 ml/100 g/min throughout the brain. Normal values are ~60 to 70 ml/100 g/min. Despite diffuse hyperemia, CBF reactivity to changes in $PaCO_2$ remain intact. CBF values ranged from 50 to 60 ml/100 g/min *(right)* in areas sampled when $PaCO_2$ was reduced to 29 mm Hg with hyperventilation. Six months after the arrest, the child was moderately disabled but not in a vegetative state.

The traditional approach to cerebral resuscitation has also recommended the use of hyperosmotic agents in the postarrest period[252]; although similar to hyperventilation, the use of hyperosmotic agents after cardiac arrest is currently out of favor. However, again studies in the setting of cardiac arrest are lacking. In dogs subjected to 6 minutes of global ischemia, mannitol (2 g/kg) further reduced CBF during the postischemic hypoperfusion phase.[253] This unwanted effect of mannitol likely represents a result of dehydration because with more conventional doses, decreased blood viscosity after mannitol administration lowers cerebral blood volume but maintains CBF.[254] A few anecdotal reports in support of the use of albumin as an osmotic agent after cardiac arrest exist,[255,256] supported by several more experimental studies in models of global ischemia.[257] Administration of hypertonic saline improves myocardial blood flow and survival versus standard resuscitation after VF in pigs.[258] These studies suggest that clinical trials examining the effect of hypertonic solutions on outcome after cardiac arrest are warranted.

In clinical practice, patients are encountered who have been successfully resuscitated from an arrest of unknown etiology, have a clinical history suggestive of trauma, or demonstrate focal pupillary findings. In this setting it is appropriate to hyperventilate or to administer mannitol until CT and clinical examination confirm the absence of trauma or a mass lesion.

Supportive Care in the Intensive Care Unit

A hypothetical algorithm for the management of infants and children after cardiac arrest is provided in Fig. 68.11. In addition to maintenance of normal ventilation, arterial oxygenation, temperature, and blood pressure, several other aspects of supportive care are important to discuss because suboptimal treatment might adversely affect outcome.

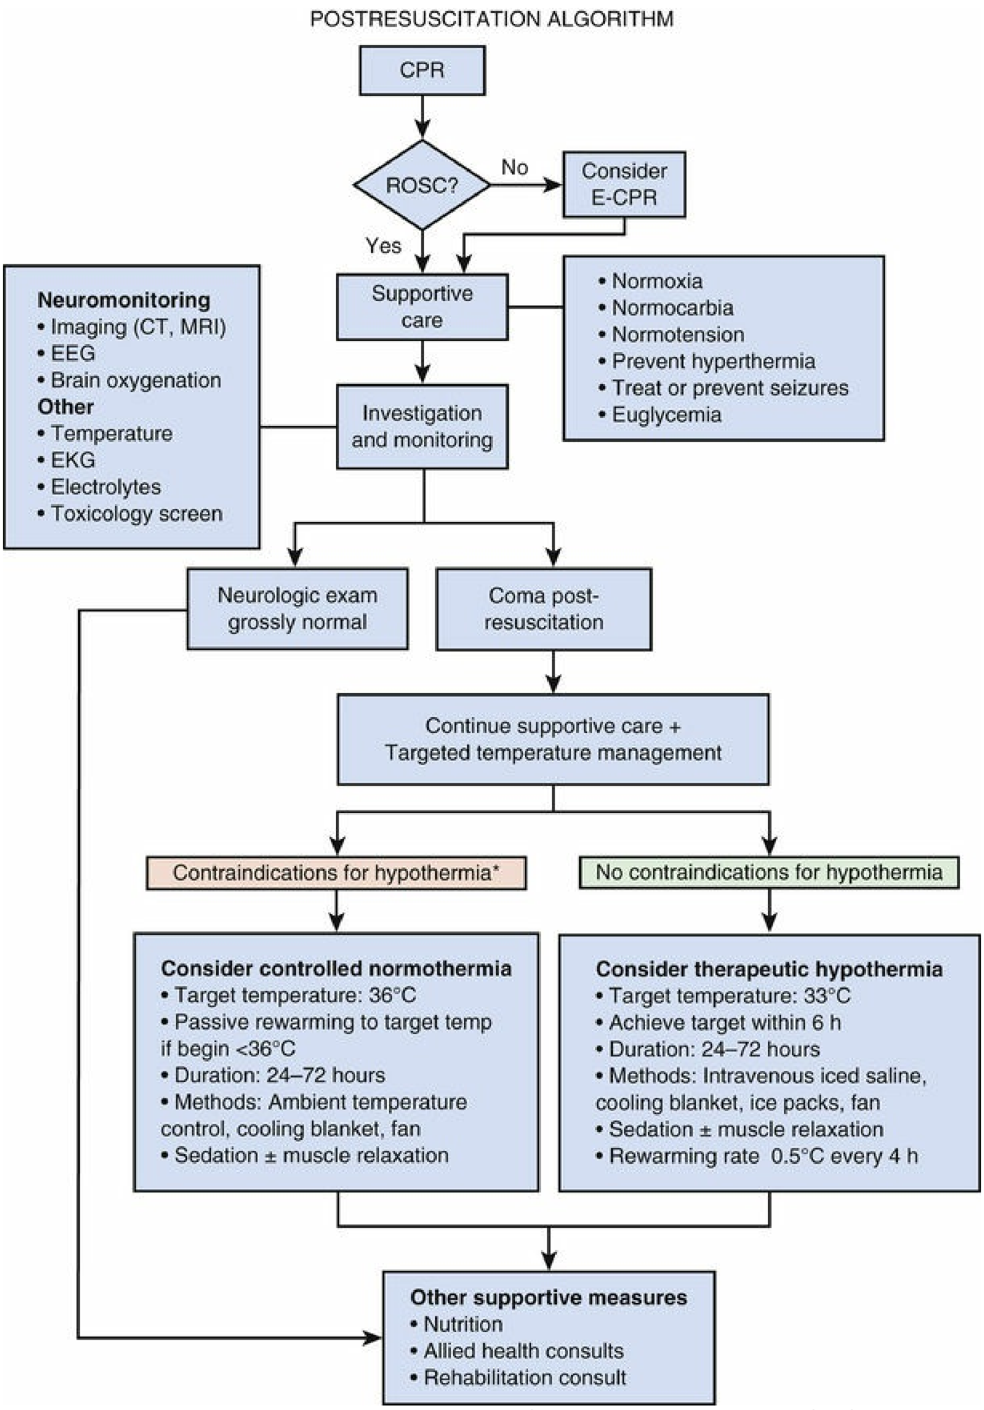

FIG. 68.11 A hypothetical algorithm for the management of infants, children, and adolescents after cardiac arrest. *Contraindications to use of hypothermia include active hemorrhage, uncorrected coagulopathy,

sepsis, and certain dysrhythmias.

There is an association between hyperoxia and outcome in both in vitro and in vivo models of brain injury, thought to be a result of increased oxidative stress.[259,260] In neonates, two systematic reviews showed a mortality benefit to resuscitating infants with room air versus 100% oxygen.[261,262] No long-term developmental outcomes were available; however, these and other data resulted in changes in the approach of neonatal resuscitation.[263]

Although neonates have lower PaO_2 prior to delivery, findings in adults with cardiac arrest may provide more insight for children. Kilgannon and colleagues found that hyperoxia (PaO_2 >300 mm Hg) and hypoxia (PaO_2 <60 mm Hg) on first arterial blood gas post-ROSC were associated with mortality in adults with cardiac arrest.[264] A study in children followed, finding an association of extreme hypoxemia (odds ratio, 1.92; 95% confidence interval, 1.80 to 2.21 at PaO_2 of 23 mm Hg) and hyperoxia (odds ratio, 1.25; 95% confidence interval, 1.17 to 1.37 at PaO_2 of 600 mm Hg) on first arterial blood gas with PICU mortality.[265] A single-center retrospective analysis found no relationship between hyperoxia or hypoxia within the first 24 hours post-ROSC with mortality.[266] Similarly, a multicenter retrospective analysis found that although derangements in oxygenation and ventilation were common, there was no association between blood gas parameters in the first 6 hours post-ROSC and survival with favorable neurologic outcome.[267] A prospective multicenter study found that oxygenation was not associated with mortality, but hypocapnia ($PaCO_2$ <30 mm Hg) and hypercapnia ($PaCO_2$ >50 mm Hg) were associated with mortality after pediatric cardiac arrest.[268] However, in a large study from Australia and New Zealand, only hypocapnia ($PaCO_2$ <35 mm Hg) was associated with mortality.[269] Pediatric guidelines written prior to availability of these pediatric data recommend resuscitation with 100% oxygen with subsequent titration of oxygen saturations to ≥94% post-ROSC.[1]

Although the optimal cerebral perfusion pattern for neuronal recovery remains to be defined,[252] blood pressure fluctuations, both high and low, adversely affect outcome. In their classic study of the neuropathology of systemic circulatory arrest in immature monkeys, Miller and Myers[225] found that systolic blood pressures at or below 50 mm Hg during the reperfusion period had devastating effects on survival and neuropathology. This occurred even when the ischemic time was less than the 12-minute minimum that caused brain injury in their model. In contrast, Bleyaert and coworkers[270] showed that intermittent episodes of hypertension (MAP 150 to 190 mm Hg) induced with norepinephrine during the first 24 hours after 16 minutes of global brain ischemia in monkeys worsened neurologic outcome. A beneficial effect of transient hypertension during the immediate postresuscitation period has been suggested,[14] hypothesizing that this improves flow in areas with microvascular sludging. Safar and colleagues[185] suggested that transient hypertension was beneficial after cardiac arrest in dogs. However, it was applied as part of a multifaceted treatment protocol, and its specific benefit remains controversial. Newer data show that in a multicenter, observational cohort of children with cardiac arrest, having a blood pressure <5% for age (56% of cohort) within the first 6 hours post-ROSC was associated with increased mortality and worse neurologic outcomes.[271] No data exist on optimal blood pressure adjuvants after pediatric

cardiac arrest.

Although seizures may be seen in 30% to 50% of children after cardiac arrest, the use of prophylactic antiepileptics is also controversial. A prospective study showed that 9 of 19 children who received therapeutic hypothermia and continuous EEG monitoring had seizures, many occurring near or during the rewarming period.[207] A small case series in children surviving cardiac arrest observed how a 7-channel EEG test evolved from the first few hours to days after resuscitation.[272] EEGs were grouped into normal, impaired, grossly impaired, and death of the brain, and the authors posited that the first EEG may not be valid for outcome prediction. The independent association between poor outcome and the presence and severity of seizures after birth asphyxia is better established.[273] There is strong rationale for treating clinical seizures postarrest; however, whether or not to aggressively treat subclinical seizures or use antiepileptics prophylactically remains to be determined.

Although transient hyperglycemia commonly occurs after resuscitation from cardiac arrest,[274] the optimal therapy or need for controlling blood glucose after resuscitation has not been established. Current recommendations are for the use of glucose-containing solutions during newborn resuscitations[275] because of evidence that hypoglycemia has synergistic deleterious effects coupled with perinatal asphyxia.[276] Dextrose-containing solutions are generally avoided in the resuscitation of the older child, given the association between hyperglycemia and poorer outcome after near drowning and TBI in pediatric patients.[172,277] Although a cause and effect relationship between hyperglycemia and outcome in humans has not been established, it is curious to note that in one of the clinical trials showing beneficial effects of hypothermia in adults after cardiac arrest, hyperglycemia was associated with hypothermic treatment.[6] However, reports of tight glucose control versus standard care in adults with VF arrest showed no difference in outcome.[278] The optimal resuscitation fluid has not been established, particularly in pediatric patients beyond the neonatal period and prior to adolescence, but is likely to be age and perhaps mechanism dependent.

Current and Novel Therapies

Postresuscitative Hypothermia

Therapeutic hypothermia has been used to treat acute brain injury for over a century.[279] Classically, the beneficial effect of hypothermia was thought to be primarily related to a reduction in oxidative metabolism. Rosomoff and Holaday demonstrated that with each decrement of 1°C, brain oxidative metabolism slows by 6.7%,[280] a finding also seen in immature rats.[281] More recently it was reported that 36°C favorably altered cellular biochemistry in cultured neurons and astrocytes, with potential for clinical translational.[282] Moderate hypothermia (31°C) during neonatal hypoxia-ischemia maintains brain glucose and ATP concentration and reduces lactate production compared with normothermia (37°C) or mild hypothermia (34°C).[281] Taken together with the well-documented effects of hypothermia on neurologic outcome in experimental models, at least a partial contribution of the effect of hypothermia on cellular energetics in affording neuroprotection after cardiac arrest is supported. However, given that mild hypothermia, which does not significantly lower oxygen consumption, provides

some degree of neuroprotection, it seems more likely that hypothermia affects multiple mechanisms that influence outcome after cardiac arrest. These mechanisms include, but are not limited to, excitotoxicity, calcium fluxes, oxidative stress, and inflammation.[283]

Although the composition of mechanisms by which hypothermia confers neuroprotection after cardiac arrest is still under debate, numerous experimental studies support further preclinical and clinical studies designed to optimize its application in humans. For instance, both applied mild hypothermia, reducing temperature by as little as 2°C,[284] and delayed spontaneous hypothermia[285] reduce neuronal death seen after cerebral ischemia in rats. Leonov and colleagues[286] reported improved neurologic recovery in dogs subjected to ice-water immersion of the cranium beginning 3 minutes after the onset of 12.5 minutes VF arrest, using CPB to maintain core temperature at 34°C for 1 hour. In this same canine VF arrest model, mild (34°C) or moderate (30°C) hypothermia was found to be protective whereas deep (15°C) hypothermia worsened cerebral and cardiac outcome.[287] Relevant to pediatric cardiac arrest, post treatment with brief (1-hour) and prolonged (24-hour) hypothermia improved neurologic outcome in a juvenile rat model and piglet model of asphyxial cardiac arrest, respectively.[190,288]

The effectiveness of hypothermia as a cerebral protective intervention (ie, prearrest) is unquestioned. The beneficial effects of hypothermia applied immediately before and during cardiac arrest are also clearly demonstrated by the clinical experience with cold-water submersion (near drowning) accident victims.[246] By contrast, complications from the use of moderate hypothermia (30°–34°C) post arrest and the apparent lack of a beneficial effect led to the abandonment of its routine application in the 1980s.[289] Randomized clinical trials in adults published in 2002 who were comatose after resuscitation from ventricular-arrhythmia–induced out-of-hospital cardiac arrest showed a beneficial effect of hypothermia (32°–34°C).[5,6] These studies prompted the International Liaison Committee on Resuscitation and the American Heart Association to recommend 12 to 24 hours of hypothermia (32°–34°C) for adult victims of VF or VT out-of-hospital cardiac arrest.[290,291] There was concern that the lack of temperature control in the normothermia or placebo groups in these two landmark studies resulted in many subjects having fever, which is known to be detrimental following cardiac arrest.[292,293] Thus a new trial was performed in adults remaining comatose after resuscitation from presumed cardiac etiology out-of-hospital cardiac arrest using active targeted temperature management (TTM) for both arms (33°C versus 36°C). They found no difference in mortality between the two groups.[10] It was noteworthy that the outcome of the control arm of this study was similar to that of the hypothermia arm in the prior hypothermia after cardiac arrest trial that demonstrated benefit of hypothermia a decade earlier. Thus a key question raised by this study is whether the prevention of fever is all that is necessary to improve outcome or whether clamping temperature at a slightly hypothermic level of 36°C confers benefit.[10] It is, as discussed, clear that even a single degree of hyperthermia produces detrimental effects on outcomes after cardiac arrest in newborns.[294] Thus this important question remains to be addressed for optimized TTM in children. Although somewhat different from a pathophysiologic standpoint, studies in neonates at risk for HIE from birth asphyxia have similarly shown that local head or whole body mild hypothermia applied for 72 hours improves survival and neurologic outcome.[3,4,295] One trial demonstrated

superior outcomes using 33.5°C for 72 hours versus longer duration (120 hours) or deeper hypothermia (32°C) for either duration.[296]

The efficacy of hypothermia for neuroprotection in neonates with birth asphyxia and in adults with VF arrest prompted some clinicians to treat pediatric victims of asphyxial or arrhythmia-induced cardiac arrest with hypothermia.[297] Two retrospective studies found that clinicians were applying hypothermia to patients with historically poor outcomes: out-of-hospital and unwitnessed arrests that required multiple doses of epinephrine for ROSC.[298,299] A multicenter, randomized prospective trial was published (Therapeutic Hypothermia after Pediatric Cardiac Arrest; THAPCA) and demonstrated no difference in survival with favorable outcome between active normothermia (36.8°C) and hypothermia (33°C) groups for children with out-of-hospital cardiac arrest (relative likelihood 1.54; 95% CI, 0.86 to 2.76; $p = 0.14$).[11] However, it should be noted that in contrast to the adult TTM out-of-hospital study where the outcomes were nearly equivalent between groups (hazard ratio, 1.06; 95% confidence interval [CI], 0.89 to 1.28; $p = 0.51$, 33°C vs. 36°C),[10] THAPCA recruited only 25% as many subjects and demonstrated a favorable point estimate for the hypothermic group. Additionally, the prevalence of asphyxia in THAPCA (72%), compared to TTM, which recruited out-of-hospital arrests of presumed cardiac etiology, may provide an explanation for the observed differences. Results for THAPCA's in-hospital pediatric cardiac arrest study, with similar randomized interventions, are pending.

Prehospital hypothermia using cold saline in adults increased the incidence of recurrent arrest and pulmonary edema and did not improve outcomes.[300] Although intraarrest cooling has shown promise in preclinical models of cardiac arrest,[301] the results of clinical trials have been disappointing[302] and the lack of clear benefit of hypothermia in pediatric cardiac arrest should limit enthusiasm for any temperature manipulation in the field unless the patient is febrile.

Therapy Directed by Grouped Characteristics

It is increasingly clear within critical care that appropriate phenotyping of heterogenous processes on the basis of physiologic, biochemical, and genetic attributes may be needed to better target therapies to the individual's situation. Within pediatric out-of-hospital cardiac arrest, infants are unlikely to have their cardiac arrests witnessed resulting in longer no-flow ischemia.[8,23] As previously described, longer no-flow times increase the risk of threshold hypoperfusion and loss of autoregulation. Thus these patients may be in greatest need of closer cerebral monitoring, although it remains uncertain this will improve outcomes. In these infants the most common cause of out-of-hospital cardiac arrest is sudden unexpected infant death (SUID). Although the pathophysiology of SUID is not singular, a substantial number of these children have evidence of autonomic dysfunction as well as neurochemical and structural brain anomalies.[303-305] Present technology precludes therapy directed at these anomalies. Preclinical studies demonstrate important differences in the pathology of brain injury,[26] which in turn may imply different neuronal cell death pathways and alterations in CBF[83] after asphyxial versus VF cardiac arrest. In addition, differences in myocardial dysfunction[306,307] and ventilation[308] between these different forms of cardiac arrest may require different management strategies to prevent secondary brain injury. In

the case of asphyxia it is clear the brain senses the insult and has a neurochemical and electrical response long before no flow,[21] which may increase the risk for excitotoxicity after resuscitation, suggesting a role for therapies such as NMDA antagonisms in these forms of arrest. Further studies of targeted therapies in targeted subpopulations of cardiac arrest are needed to better define the differences suggested by these preliminary studies.

Inhibition of Postischemic Excitotoxicity

The observation in animal models that hypermetabolism accompanies postischemic hypoperfusion formed the basis for early clinical cerebroprotective strategies in the postarrest setting. Therapies directed at attenuating active cerebral metabolism (resulting from synaptic transmission) were applied in the hope of reducing this secondary insult of hypoperfusion plus hypermetabolism. The cerebral protective effects of interventions that decrease cerebral metabolic rate *before* the onset of ischemia, such as barbiturates and hypothermia, are well established and clinically important.[309,310] The selective inhibitory effect of barbiturates on active $CMRO_2$ was particularly attractive. However, therapeutic reductions in brain metabolism when applied *after* the insult, as in the *HYPER* therapy of the 1970s and 1980s, did not improve outcome.[289,311] This may have been the result of the relative lack of postarrest hypermetabolism in human beings.[169] In addition, adverse hemodynamic consequences of barbiturates and the ill effects of sustained hypothermia on immune function and blood rheology may have counteracted any beneficial effects. More targeted therapies may need to be developed. As previously outlined, agents inhibiting extrasynaptic neuronal death pathways or CaMKII may have promise in protecting against neuronal death.[89,312]

Futuristic Approaches

Mitochondria Targeting Strategies

Therapies targeting mitochondria can be divided into (1) alternative fuels, (2) inhibitors of mitochondrial permeability transition (MPT), and (3) mitochondria-targeted electron scavengers and antioxidants. Among the first category, acetyl-L-carnitine was shown to potentiate normalization of brain energy metabolites and improve neurologic outcome after complete global cerebral ischemia reperfusion.[313] Experimental studies in cardiac arrest report improved myocardial function and reduction in neuronal damage with an MPT inhibitor cyclosporine when administered at the time of reperfusion or shortly thereafter.[314-316] In contrast to the first two strategies, the third class of therapies will selectively accumulate in mitochondria and bind targets within the organelle to exert their effects.[102] Several strategies have been used to effectively target mitochondrial localization of small molecules including conjugation to lipophilic cations such as triphenylphosphonium that take advantage of negative membrane potential of mitochondria[102] and bind to a specific mitochondrial target such as cardiolipin, a phospholipid exclusively found in the inner mitochondrial membrane.[70] Only one compound in the first category has been tested in cardiac arrest. Administration of mitochondria-targeted sulfide donor AP39 at the time of CPR or 1 minute after ROSC was shown to improve neurologic

function and long-term survival rates after an 8-minute cardiac arrest induced by potassium chloride in adult mice.[317] Compounds in the second category include Szeto-Schiller (SS) peptides.[104] Their uptake into mitochondria is thought to be independent of membrane potential with a high affinity binding to the inner membrane.[104] They contain four alternating aromatic amino acids and some have antioxidant activity. One of these peptides, SS-31, protects mitochondria, accelerates ATP recovery, and reduces infarct size in the heart.[104] Another class of compounds in the second category promising for pediatric cardiac arrest is made up of the hemigramicidin-nitroxides (GS-nitroxide) inspired by the shared ancestry between mitochondria and bacteria, taking advantage of chemical moieties used in antibacterial agents (the antibiotic gramicidin S) with high affinity for the cardiolipin-rich inner mitochondrial membrane.[105] One GS-nitroxide, XJB-5-131, was shown to partition almost exclusively into neuronal mitochondria in vitro, penetrate the blood-brain barrier, prevent cardiolipin oxidation and caspase activation, and improve neurocognitive outcome after asphyxial cardiac arrest in juvenile rats.[103]

Erythropoietin

Erythropoietin (EPO) is better known for its bone marrow stimulation effect,[318] but it is also required for normal brain development, stimulating neural progenitor cells.[319,320] EPO used therapeutically in experimental models of neonatal hypoxia-ischemia has multiple potential mechanisms of neuroprotection, including prevention of apoptosis, protection from oxidative stress, modulation of cellular water permeability, and promotion of neurogenesis and angiogenesis.[319,321,322]

Therapeutic hypothermia has become standard of care for newborns with moderate/severe HIE,[323] leading investigators to find other therapies that complement or synergize with hypothermia. Combination therapy with hypothermia and EPO shows promise in experimental models, improving sensorimotor function, with 7-day-old female rats benefiting more than males.[324] In a nonhuman primate model of perinatal asphyxia, combination therapy produced superior results over placebo and hypothermia alone in terms of the primary outcome, death, or moderate-severe cerebral palsy.[325] Pilot studies have demonstrated pharmacokinetics, feasibility, safety, and, in some instances, improved outcomes.[326-330] Efficacy of combination therapy is now being explored in a multicenter randomized controlled trial (RCT; NCT01913340).

Stem Cell Therapy

Pluripotent stem cells have the capacity to differentiate into cells with antiinflammatory, immune-modulating, and potentially neuroprotectant properties.[331] In experimental brain injury models, stem cells have been shown to localize to injury regions, express neuronal and glial markers, reduce cell death, increase CNS cellularity, and improve outcomes.[332-335] Treatment efficacy was affected by method of delivery (ie, intracerebral, intravenous), timing, frequency, type of stem cell, and model, with some reports having neutral effects on outcome and others having adverse effects such as brain tumor development.[336,337]

A pilot study in which autologous umbilical cord blood was transfused in neonates with birth asphyxia who also received hypothermia therapy did not reveal

serious safety issues.[338] At least one RCT is actively recruiting newborns to determine further safety and feasibility of stem cells in this cohort (NCT00593242). Preliminary studies in children with cerebral palsy show promise in safety and feasibility.[339-341] An RCT evaluating umbilical cord blood transfusions in combination with EPO showed improvement in motor and cognitive functioning.[342] One RCT using autologous umbilical cord blood for treatment of cerebral palsy is actively recruiting patients (NCT01147653).

Extracorporeal Support

Extracorporeal support in the form of CPB initiated immediately after VF arrest in dogs (with cannulae already in place) improves outcome when compared to standard advanced cardiac life support–guided resuscitation.[343] CPB produced 64% survival after even 20 minutes of VF arrest, although all dogs were neurologically impaired. This supports the concept that cerebral and coronary perfusion during CPR extends tolerated insult time, although studies with vascular cannulation during resuscitation have not been reported. These studies would be important in light of the difficulty in obtaining this type of vascular access during arrest in children. Nevertheless, extracorporeal support allows control of postarrest blood flow and temperature, and the cardiovascular support provided might allow use of otherwise contraindicated therapies.

Many studies have shown that rescue extracorporeal life support (ECLS) or E-CPR is feasible under varied circumstances. This intervention is detailed in Chapter 59.

Summary

The social and economic impact of children left with persistent neurologic injury after cardiac arrest remains staggering. Preventive approaches to this problem are unlikely to reduce significantly the occurrence of these multifactorial and largely unanticipated events. However, it is worthwhile for the general public to become more knowledgeable of child CPR, safety measures (eg, pool and road safety), and the enormous benefit of quality CPR[344] and to consider implementation of systems that recognize a hospitalized child in distress before an arrest is imminent, such as pediatric medical emergency teams.[345] Improvements in prognostication after cardiac arrest are on the horizon with a more concerted application of existing methods and new techniques. The successful application of novel brain-oriented therapeutic approaches is somewhat more speculative, but it is likely to require intervention beginning in the prehospital setting or emergency department. Improved, pathophysiology-guided stratification of postarrest patients is essential to determine which patients have resuscitable insults and, with optimal supportive care and prevention of secondary neuronal deterioration, potential for a good rather than devastating outcome. Unfortunately, this group is unlikely to include most patients with prolonged asphyxial arrest and in any single institution represents a small number of cases per year. Biochemically and physiologically guided, multifaceted pharmacologic and mechanical approaches will almost certainly be required, with their application based on the temporal sequence of pathologic events.

Acknowledgment

This chapter remains dedicated to Peter J. Safar, the "father of modern-day CPR," who passed away on August 3, 2003. *Rest in Peace.*
